

Historical solar Analysis from Long-term geosynchronous Orbit

A proof of concept study to use CM SAF's MAGICSOL method to retrieve global and direct surface radiation from historical geosynchronous observations

1. Introduction

The last century and the last decades in particular have been witness to dramatic, anthropogenically caused changes to the Earth's climate systems. In light of these transformations, it is increasingly important to understand our planet's energy budget. The in- and outflows of radiative energy, as well as their spatiotemporal distribution, play an essential role in the earth's climate (World Radiation Monitoring Center – Baseline Surface Radiation Network 2012a). Understanding them is also crucial for planning and exploiting solar energy, which can in part be used as a mitigation strategy against anthropogenic climate change (Huld et al. 2010). Additionally, solar irradiation data can be used to better understand ecological processes (Jacobson, Seaver, and Jiashen Tang 2011) and in agricultural and hydrological applications (Otkin et al. 2005).

The Global Climate Observing System (GCOS) has identified solar irradiance, the surface radiation budget and cloud properties as essential climate variables (ECVs) (Global Climate Observing System 2012). Three factors used to measure these variables are surface incoming shortwave radiation (SIS, also known as global irradiation), surface incoming direct radiation (SID, also known as direct or beam irradiation) and effective cloud albedo (CAL). GCOS has called for the international exchange of historical measurements and the systematic observation of these variables in the present.

Despite the importance of these variables, current global data sets have several deficits. Ground measurement techniques are expensive and concerted efforts have failed to establish uniform measurement schemes (Hegner et al. 1998). Furthermore, due to the high spatiotemporal variability of these ECVs, a very dense network of ground stations would be necessary to generate high-quality, spatially continuous data (Hammer 2001). Model-based computations often require large amounts of input data and produce results missing necessary variables or with insufficient accuracy to qualify as ECVs (e.g. Berrisford et al. 2009). Satellite retrievals are highly accurate, but currently available data sets fail to provide all three of the above mentioned ECVs in high resolution on a global scale (R. Posselt et al. 2012).

In light of the high accuracy of satellite-based solar ECV retrievals, it is proposed that archived, historical data from geosynchronous orbit could be used to produce a global ECV data set. Some global solar irradiation data sets already exist. For example, Lohmann et al. (2006) used data from the International Satellite Cloud Climatology Project

(ISCCP) to retrieve surface incoming global and direct radiation on a global scale. These data, however, is reduced from the native resolution of the geostationary satellites that produced the imagery to the resolution used in ISCCP. R. W. Mueller et al. (2009) used Advanced Very High Resolution Radiometer (AVHRR) data collected onboard the National Oceanic and Atmospheric Association's (NOAA) Meteorological Operational (MetOp) satellites to retrieve surface incoming shortwave radiation, but using these satellites to retrieve effective cloud albedo and surface incoming direct radiation is problematic due to the low temporal resolution of the polar orbiting satellites.

A new global ECV data set is needed that overcomes these deficits. Its data requirements should be robust enough to allow retrievals of solar direct and global irradiance, as well as cloud albedo, from a variety of different sources without needing large amounts of ancillary data, which might not be available. It should also provide data in high resolution, on a global extent and homogeneously over a time period long enough for climate studies. Finally, the data set should, if possible, be openly available in order to maximize its usability in both commercial and research-oriented projects.

In this study, the feasibility of a global, high-resolution data set of surface incoming shortwave and direct radiation, as well as effective cloud albedo, is evaluated using the MAGICSOL method (R. Mueller, Trentmann, Stöckli, et al. 2011). The MAGICSOL method has been tested extensively and with a large degree of success for the Meteosat satellites (R. Posselt, Müller, Trentmann, et al. 2011). Because the MAGICSOL method uses a self-calibrating technique to compensate for satellite changes and sensor degradation, it is hypothesized that it will work effectively with imagery acquired onboard the GOES satellites, which use similar sensors to those on board the Meteosat First Generation satellites, which were used by R. Mueller, Trentmann, Stöckli, et al. (2011) to produce the CDRs in question from Meteosat imagery. Meteosat and GOES imagery is available from the 1980s, making it possible to produce a climate-quality data set from archival data, should the method prove effective with the GOES satellites. It is furthermore proposed that using the MAGICSOL method makes it possible to produce higher quality data than is available from other sources.

In order to test this hypothesis, one month of data from all available satellites in the geo-stationary ring was used to retrieve effective cloud albedo and surface incoming shortwave and direct radiation. The data was validated using ground-based measurements with the goal of reaching the European Organisation for the Exploitation of Meteorological Satellites

(EUMETSAT) Satellite Application Facility on Climate Monitoring (CM SAF) Continuous Operations and Development Phase (CDOP) accuracy standards (R. Posselt et al. 2012). It was also compared with data produced from other sources, namely the ERA-Interim reanalysis data and the AVHRR-derived CLARA data set (see chapter 2).

Table 1.1: Accuracy targets for direct and global irradiation (R. Posselt et al. 2012).

	Total shortwave radiation (W/m ²)			Direct radiation (W/m ²)		
	Threshold	Target	Optimum	Threshold	Target	Optimum
Monthly	15	10	8	20	15	12
Daily	25	20	15	30	25	20

The following chapters provide an overview of currently available data. In the next chapter, the data that was used is introduced. Following that, the MAGICSOL algorithm, as well as the validation techniques used, are explained. Thereafter, the results of the retrieval are shown and validated, both qualitatively and quantitatively. Finally, the possibility of producing the global CDRs in question from geostationary satellites is discussed, with considerations of the possibility of using additional data sources. The study is concluded by an outlook on further possibilities for improvement and possible areas of research.

2. Current data sets and retrieval methods

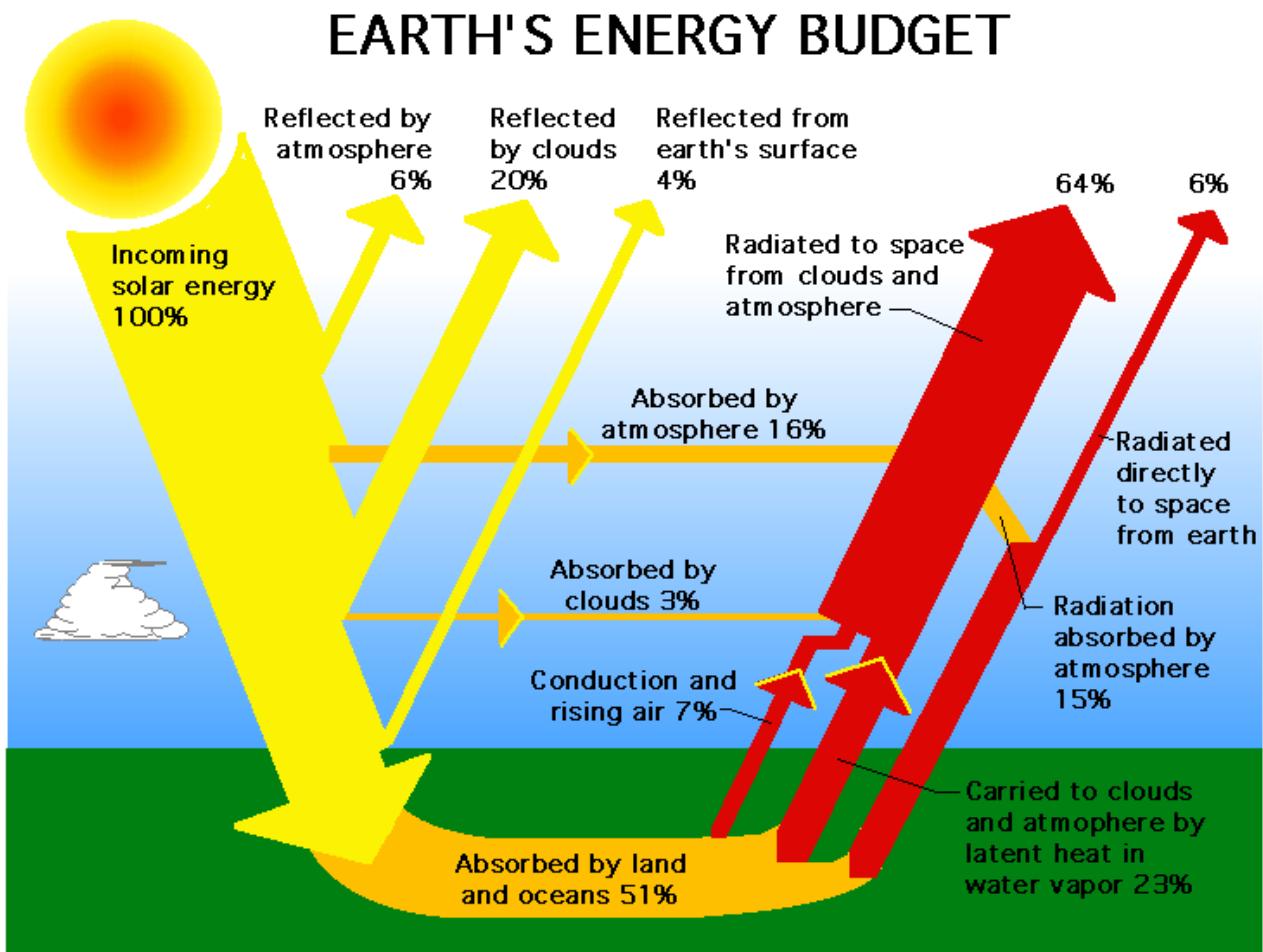

Figure 2.1: A schematic diagram of Earth's energy budget (Madigan 2011).

The main components of the earth's radiation budget are well known and the rough amounts of energy that are passed from each system component to another are fairly well understood on a global, long-term scale (see figure 2.1). Three of the most important components are effective cloud albedo, surface incoming solar radiation and surface incoming direct radiation (see figure 2.2). These essential climate variables are the focus of this study.

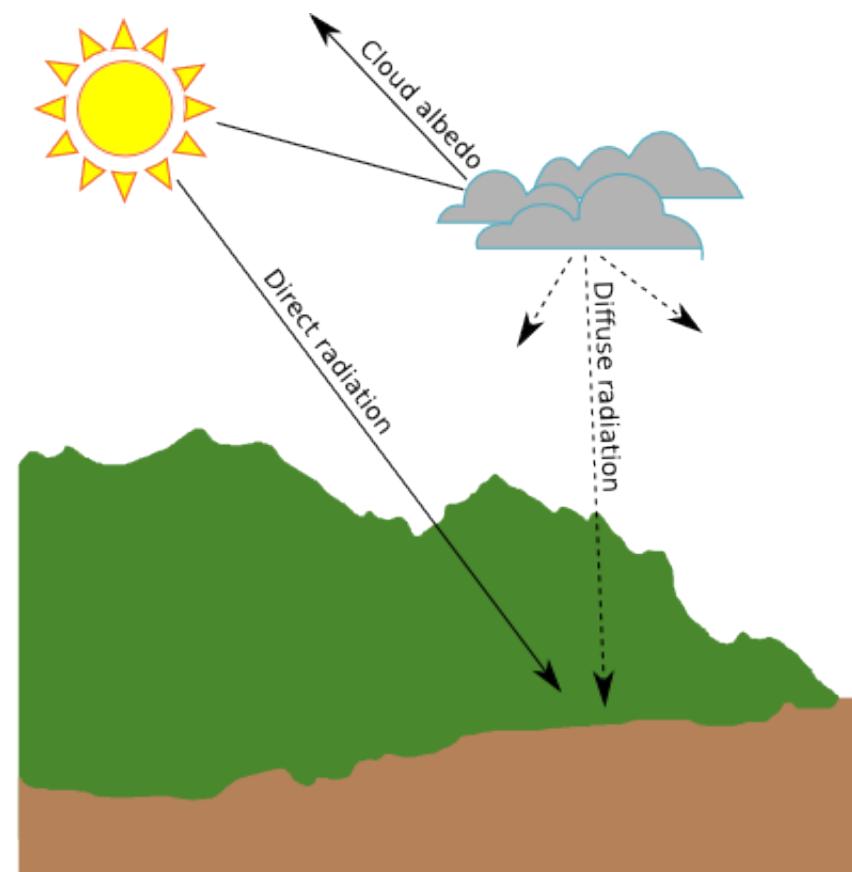

Figure 2.2: The essential climate variables examined in this study. Total shortwave radiation is the sum of diffuse and direct radiation. Modified by author, based on: (Department of Primary Industries, State Government of Victoria 2011).

Each of these ECVs is tied closely not only to cloud cover, but also to cloud types (Deneke, Feijt, and Roebeling 2008). This makes them highly spatially variable, as not only the latitude and season, but also local topography, prevailing winds, air moisture, and other atmospheric factors strongly influence them (see figure 2.3). The ECVs are not only spatially, but also temporally highly variable - Lohmann et al. (2006) showed that solar irradiation is highly variable in time as well, so that long time series are necessary in order to accurately describe the irradiation that should be expected at a given location (see figure 2.4).

Great uncertainties still exist concerning solar irradiation and cloud albedo over the world's oceans (R. Mueller, Trentmann, Träger-Chatterjee, et al. 2011). As these areas make up most of the earth's surface, understanding their contributions to the global radiation budget are crucial to quantifying past and predicting future climate change (United Nations 2007).

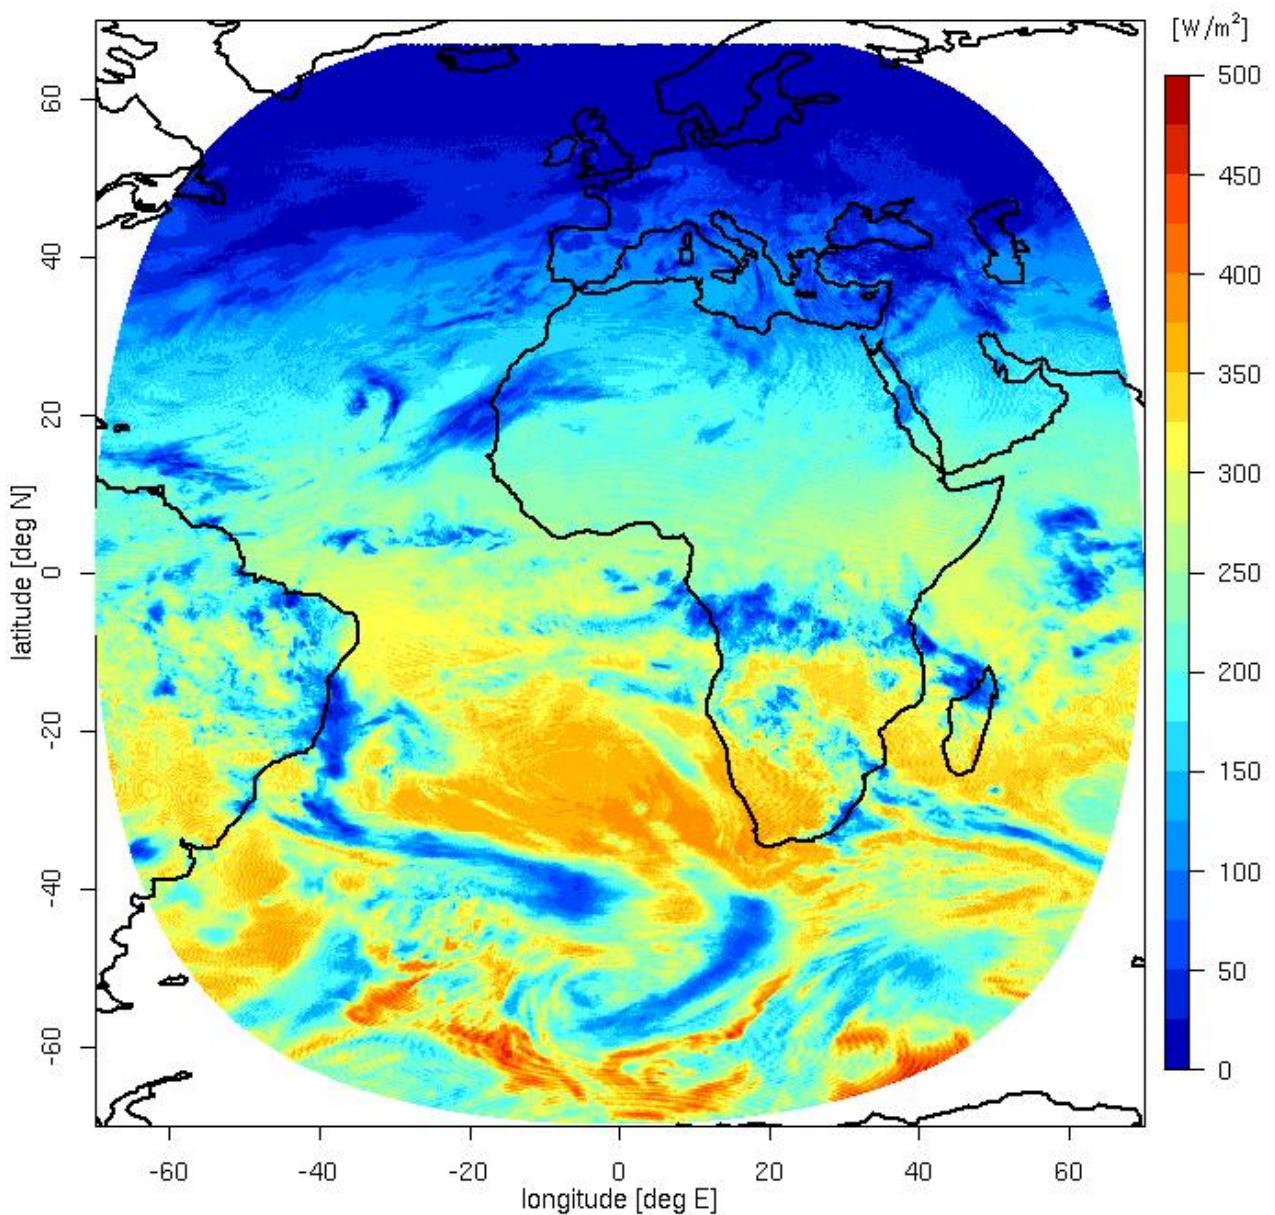

Figure 2.3: Daily average of total surface incoming shortwave radiation on January 1 1983, derived from Meteosat First Generation imagery. Total surface incoming radiation is the least variable of the three ECVs in this study and is nonetheless highly variable, not only longitudinally but also on other scales (R. Posselt, Müller, Stöckli, et al. 2011).

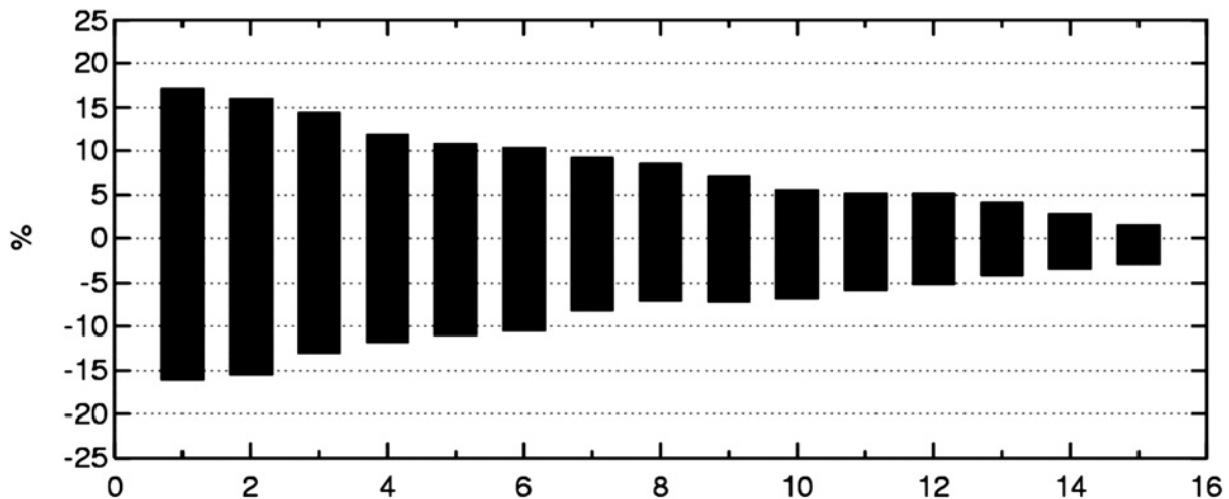

Figure 2.4: Minimum & maximum deviations from 18 year mean when averaging over limited time spans. The x axis describes the number of years used to produce an average, the y axis the deviations from the 18 year mean. Using time series with less than seven years results in deviations from the 18 year mean of more than 10% (Lohmann et al. 2006).

In the following sections, current relevant measuring techniques are introduced, as well as available data sets with their respective advantages and disadvantages.

2.1. **Ground based data**

Ground-based data have several advantages compared to other types of data. The measurements are performed directly, rather than being derived as secondary data, and the instrument calibration can be tested if needed. For this reason, ground-based measurements are often considered to be reflect the truth and are used for validation when testing other measurement techniques.

There are several drawbacks associated with ground-based measurements. As with almost every type of ground-based measurement, the instruments needed to measure solar global and direct irradiation only provide information about the point at which the measurement took place, so that it is difficult to use them for applications that require spatially continuous data. Cloud albedo cannot be measured from the ground directly, and the instruments necessary to measure solar global and direct irradiation are expensive compared to other meteorological instruments (e.g. Omni Instruments 2012). Because careful calibration and frequent maintenance for the instruments is required, it would be prohibitively expensive to establish a dense, widespread network of ground stations (Bureau of Meteorology, Commonwealth of Australia 2012).

Despite these disadvantages, ground stations are an important and necessary part of the global infrastructure needed to observe solar ECVs due to their role as providers of ground truth data.

2.1.1. Measurement techniques

Because the ECV cloud albedo refers to the reflection of sunlight from clouds into space without striking the earth, there is no way to measure it directly from the ground. Both solar global irradiation and solar direct irradiation can, however, be measured using ground-based instruments.

Figure 2.5: A research-grade pyranometer (Wikimedia Commons 2012b).

Figure 2.6: A research-grade pyrheliometer (Wikimedia Commons 2012a).

Global irradiation is measured on a horizontal surface using pyranometers. Pyranometers operate by measuring changes in temperature on a black surface using thermocouples. In order to insulate the sensing element from non-radiative temperature changes, the sensor is shielded by two glass domes (see figure 2.5). When radiation strikes the pyranometer's sensing element, it produces heat, which flows into the cooler pyranometer body. The temperature difference between these two elements creates an electromotive force which is measured and recorded as an indicator of the irradiance occurring at a given point in time (Bureau of Meteorology, Commonwealth of Australia 2012).

Global irradiation measurements with pyranometers are subject to various errors. The degree to which the sensing element is heated is dependent on the conversion of radiative into thermal energy. The energy is absorbed by a black paint on the sensing element, which should optimally absorb all wavelengths equally. However, as the paint degrades over time, this can change, so that certain wavelengths are absorbed less effectively. This

decreases the total amount of irradiation measured (Bureau of Meteorology, Commonwealth of Australia 2012). As the sensor degradation is a result of many processes, it must be compensated by recalibrating the device. There are many methods to do this, and all of them require a high degree of knowledge about calibration techniques and direct work with the individual device (Reda, Stoffel, and Myers 2003).

Further limitations are posed by the device design itself. The thermal absorption ratio of the sensing element decreases as the solar incident angle increases. As pyranometers measure irradiation on a horizontal surface, the irradiation at low solar altitudes is measured with a negative bias (Bureau of Meteorology, Commonwealth of Australia 2012). Furthermore, the insulating domes protecting the sensing element from undesired temperature changes are composed of glass which both reflects and absorbs radiation. Thus, the insulators both prevent some radiation from reaching the sensor, while also exchanging radiation with the sensor itself. Additionally, dust or other obstructions on the insulating dome affect the amount of irradiation the pyranometer observes (Srivastava 2009).

Solar direct irradiation is more difficult to observe than solar global irradiation due to the fact that direct irradiation is only the radiation traveling directly between the sun and the measuring instrument. It is measured as the solar energy reaching a plane perpendicular to the sun's direct beam on the earth's surface. This is accomplished by using pyrheliometers with a viewing angle of 5° (see Figure 2.6). The pyrheliometer must be mounted on a solar tracker to ensure that it is continuously pointed at the sun (Bureau of Meteorology, Commonwealth of Australia 2012).

Field pyrheliometers operate according to the same principle as pyranometers and are thus subject to most of the same errors. Pyrheliometer calibration is even more labor intensive than pyranometer calibration, requiring two to three days of testing. Each day, 100 one-minute measurements are compared between the field pyrheliometer and a stable, self calibrating cavity radiometer (Flowers 1978).

2.1.2. Data sets

High-quality ground-based solar measurements are hard to obtain. Most databases are comprised of collections of measurements gathered at single stations. Few contain pyrheliometer data, so that the data from many stations is often restricted to only global irradiation.

Noteworthy point databases include the National Solar Radiation Data Base from the U.S. Department of Energy's National Renewable Energy Laboratory, which is comprised of hourly measurements of global irradiation collected at 237 stations from 1961-1990 and measurements of solar global and direct irradiation collected at 1,454 stations from 1991-2005 (U.S. Department of Energy, Office of Energy Efficiency and Renewable Energy, National Renewable Energy Laboratory 2008). The National Solar Radiation Data Base is free to use for any purposes, but is only available for the United States.

The European Solar Radiation Atlas (ESRA) contains station measurements collected across Europe from 1981-1990 by the World Radiation Data Centre (WRDC) and various other institutions (Page et al. 2001). These measurements were conducted in varying degrees of quality – monthly averages of global irradiation are available from 586 stations, whereas daily sums of global irradiation are only available from 90 stations. Six stations provide daily solar direct irradiation values. The data are also available as spatially continuous monthly average rasters and one yearly average raster with a resolution of approximately 10 km. These were computed by interpolating the monthly averages of solar global and direct irradiation from all stations. At stations where direct irradiation was not measured, it was computed using empirical formulas. The raster data is rated with an uncertainty of 25 Wh/m² (Scharmer and Greif 2000), well below the CM SAF quality threshold used in this study (R. Posselt et al. 2012).

Another spatially continuous solar data set created from ground measurements is the Joint Research Centre's Photovoltaic Geographical Information System (PVGIS). PVGIS-3 was created by using spline interpolation on the monthly station measurements contained in the ESRA database and contains monthly averages of solar global and direct irradiation for all of Europe with a resolution of 1 km. Linke turbidity maps were used to help estimate the proportion of direct irradiation from the global irradiation (Huld et al. 2010). Satellite data from the HelioClim project (described in chapter 2.3.2) were used for the Mediterranean Basin, Africa and southwest Asia (Huld and Dunlop 2012a). In validation tests, the PVGIS-3 database has a similar root mean square error as the ESRA database, with better performance in winter. This is most likely due to the fact that PVGIS also considers shadowing effects, which were not used for the ESRA database (Huld and Dunlop 2012b). It should be noted that the new version of PVGIS, PVGIS-4, now uses satellite data rather than station measurements due to the higher data quality and the increased ease in keeping the database current (Huld and Dunlop 2010).

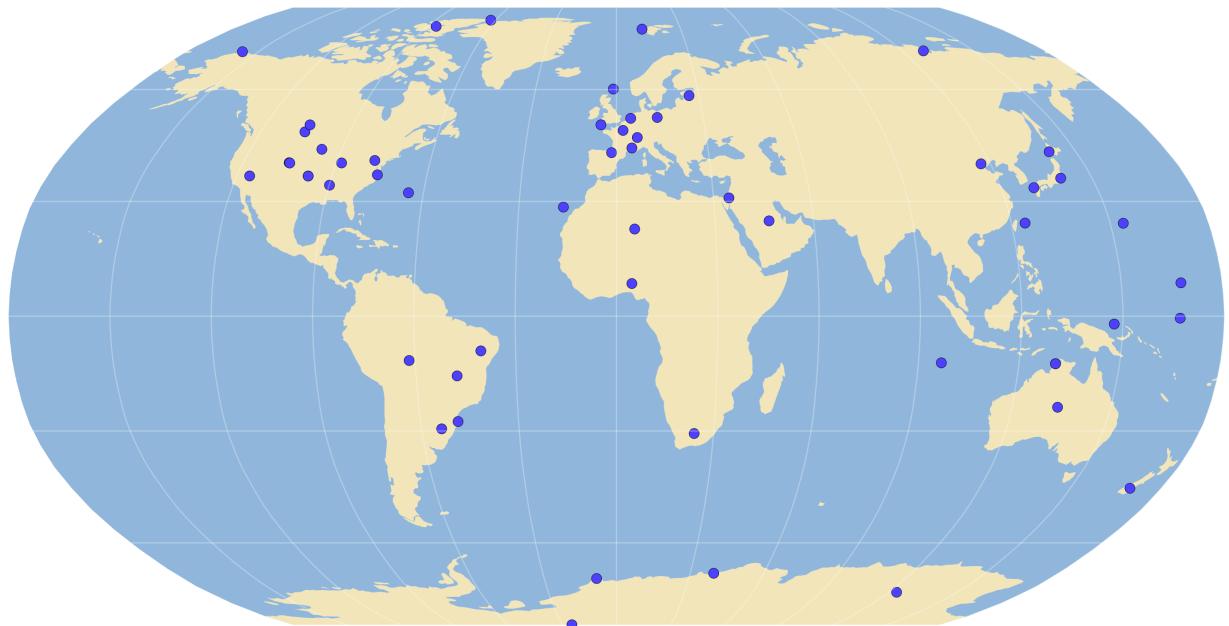

Figure 2.7: BSRN stations currently in operation. Based on: (Ohmura et al. 1998).

The Baseline Surface Radiation Network (BSRN) is a high quality radiation monitoring network operated by the World Climate Research Programme (WCRP) as part of the Global Energy and Water Cycle Experiment (GEWEX) (World Radiation Monitoring Center – Baseline Surface Radiation Network 2012a). It is comprised of 56 ground measuring stations distributed throughout the world (see figure 2.7). The measurements are centrally archived at the World Radiation Monitoring Center and subjected to quality controls (Hegner et al. 1998). Each station observes several essential measurements of radiation, synoptic weather and the upper atmosphere. These essential measurements include solar global and direct irradiation. Additionally, many stations measure expanded variables (World Radiation Monitoring Center – Baseline Surface Radiation Network 2012b). The BSRN is considered one of the highest quality global available, research-grade radiation networks.

2.2. **Reanalysis data**

Reanalysis data is produced by assimilating past observed data into complex, predictive weather models. The large amount of available historical data can be modeled using a unified modeling scheme, producing consistent model outputs of variables that cannot be measured directly or with such high resolution over a long period of time. This makes it possible to effectively simulate data for a point of time in the past that was not or could not be measured.

Reanalysis offers many possibilities in the context of cloud albedo and solar irradiation, especially as opposed to operational numerical weather prediction. Because a single model is used over a long time period, no inhomogeneities are introduced into the output data through changes in the model or the data assimilation scheme. Additionally, data can be produced that extends far into the past rather than only into the near future.

However, as with all modeling applications, reanalysis is subject to uncertainties. For example, each model step is only as good as the data it is given. This means that low data quality due to poor instrument setup, degraded instruments, instrument changes or the like, leads to poorer results. The model skill is also of concern – uncertainties in the model are propagated into the output data.

Reanalysis is also very computationally expensive, as it requires the use of a dynamic circulation model. Its input data are very high. The high computational costs and often low data input density lead necessarily to low resolution outputs, making it difficult to utilize reanalysis data in local or regional applications.

In principle, reanalysis data could be produced using regional climate models for single regions and smaller areas, but in practice most reanalysis data is made using general circulation models on a global scale. In the following sections, some of the main tenets of these models are briefly described, as well as relevant global data sets.

2.2.1. Computation techniques

An extended discussion of circulation modeling techniques would go beyond the scope of this study. For additional information on general circulation models and numerical weather modeling in general, see e.g. Satoh (2004) or Warner (2011).

For the scope of this study, it should suffice to say that numerical weather models simulate complex exchanges in pressure, air mass, temperature, moisture, kinetic energy, etc. The level of complexity is limited only by the developers' understanding of the modeled systems and the available data. For example, drag, albedo and moisture exchange of the earth's surface can be simulated in circulation models and, if desired, they can be coupled with e.g. ocean models to more accurately model exchanges of heat, moisture and materials with the ocean, as well as with regional climate models to more accurately model occurrences on a regional scale.

Generally, cloud albedo is not included as an explicit output in reanalysis data sets.

Downward solar global and (sometimes) direct irradiation is most often modeled by computing the transmittance and refractive properties of the simulated atmospheric column (e.g. Matricardi et al. (2004)).

2.2.2. Data sets

Due to the high amount of computing power required to produce reanalysis data, only institutions with large resources are able to produce them. Some of these data are only available for certain spatial domains. For an up-to-date, systematic comparison of most available reanalysis data sets, including those with a limited spatial domain, see Reanalysis Intercomparison and Observations (2012). Due to the global nature of this study, only global data sets will be introduced in this section.

The Japanese 25-year Reanalysis (JRA-25), produced by the Japanese Meteorological Agency (JMA) and the Central Research Institute of Electric Power Industry (CRIEPI), is available for the years 1979-2004 and is continued into the present through the JMA Climate Data Assimilation System (JCDAS). Its primary data source is from satellites, using geostationary observations to compute wind vectors and retrieving brightness temperatures from the TIROS Operational Vertical Sounder (TOVS). Precipitable water and other data are adjusted according to satellite and ground-based observations using a three-dimensional variational method (3D-Var). All fields are provided with a resolution of 1.25° on a 6-hourly basis. Surface solar global irradiation is included among the output data (Onogi et al. 2007).

The National Centers for Environmental Prediction (NCEP) and National Center for Atmospheric Research (NCAR) have produced several reanalysis data sets, including the NCEP/NCAR Reanalysis I (R1). This data set provides 6-hourly outputs which include surface solar global and direct irradiation (US Department of Commerce 2008). Several data sources were assimilated for the reanalysis, including measurements conducted on ships, airplanes, radiosondes, ground stations and satellites. The initial input data is quality controlled and is extended into the future with a horizontal resolution of 2.5° (Kalnay et al. 1996).

The National Aeronautics and Space Administration (NASA) also maintains a reanalysis data set comprised of data from 1979 to the present. Titled Modern Era Retrospective-Analysis for Research and Applications (MERRA), the reanalysis data is produced using the Goddard Earth Observing System (GEOS-5) Atmospheric General Circulation Model

(AGCM). The data set has the highest resolution among global reanalysis data sets (0.6° longitude $\times 0.5^\circ$ latitude) (Rienecker et al. 2011). Surface solar global irradiation is computed with consideration of simulated absorption and scattering from water vapor, ozone, oxygen, carbon dioxide, clouds and aerosols (Chou and Suarez 1999).

In Europe, the European Centre for Medium-Range Weather Forecasts (ECMWF) produces reanalysis data as a part of the ERA (ECMWF Reanalysis) project. The ERA-Interim data set provides surface solar global irradiation at 6-hour intervals (European Centre for Medium-Range Weather Forecasts 2012). Observational data from ground stations and satellites, both geosynchronous and polar-orbiting, is assimilated into the reanalysis using a four-dimensional variational (4D-Var) analysis scheme encompassing data from 1979 to the present with plans to eventually cover the entire 20th century (Dee et al. 2011). Irradiation is simulated using a fast radiative transfer model, Radiative Transfer for the Television Infrared Observation Satellite (TIROS) Operational Vertical Sounder (RTTOV). The model computes aerosol optical depth from the model's simulated temperature, water vapor, ozone and surface emissivity (Matricardi et al. 2004). The data is available in a user-specified resolution up to a resolution of 0.75° (Uppala et al. 2005).

All of the listed reanalysis data sets are considered to have a high quality and their global coverage is quite useful in many applications. However, the data is subject to the compound weaknesses of the data ingested and the models used. Additionally, their low spatial resolution limits their usage to global applications, making them unable to meet the requirements for global ECV data sets outlined in chapter 1.

2.3. *Satellite based data*

Satellites observe the earth using electromagnetic radiation. Radiation data produced using satellite observations can be seen as a mixture between direct measurements and more abstractly derived data, similar to reanalysis data. Because satellites are only able to directly observe the radiance of a given area in their field of view, climate variables have to be computed indirectly by using some kind of model in order to retrieve them from satellite data. These models are most often several orders of magnitude simpler than the weather models used to produce reanalysis data and require less data to operate.

Obtaining climate data from satellite observations has several advantages. Unlike reanalysis data, which is computed indirectly using several simulated variables, satellite data often has a more immediate relationship to observational data. This reduces the risk

of compound errors producing biased data. In contrast with ground-based measurements, satellites make spatially continuous measurements, eliminating the need for modeling or interpolation to fill spatial gaps in data sets. Additionally, a single instrument can be used to image large portions of the earth's atmosphere or surface, reducing the uncertainty caused by using measurements from several different instruments that may or may not be properly intercalibrated.

One would be mistaken, however, to attempt to use satellite data as a sole data source. One problem is that satellites cannot reach the temporal resolution of high-quality ground-based instruments. Polar orbiters rotate the earth around the poles and can need days to image the same portion of the earth's surface twice. This disadvantage is compensated in part by their high resolution – their low orbit forces them to sacrifice a wide viewing angle for a higher spatial resolution. Geosynchronous satellites maintain a stable position above a point on the equator and thus can image more frequently, but in order to keep station they have to orbit farther away than polar orbiters, thus lowering their spatial resolution. Geosynchronous satellites have the advantage that they can image their entire field of view in an hour or less, although not all satellites work with this schedule. Climate variables derived from satellite observations should be validated using ground-based data if possible, in order to verify that the sensor on board the satellite and the model used to compute the variable are functioning correctly.

Despite these disadvantages, the advantages of satellite data make a strong case for basing a global solar ECV data set on satellite observations. Their spatial resolution is sufficient for mesoscale applications and the spatially continuous measurements validate better than data interpolated between stations. Also, because satellites are located above clouds, they are able to measure cloud albedo more directly than any other technique. These are the main reasons that satellites were chosen as the data source of choice for this study.

2.3.1. Retrieval techniques

Satellites observe climate variables by examining electromagnetic radiation that is emitted by or reflected from the earth and the atmosphere. This presents several difficulties when attempting to measure solar irradiation at the earth's surface, as well as when measuring cloud albedo. In order to overcome these shortcomings, models of varying complexity must be used in order to compute the amount of radiation reaching the earth's surface and

the amount reflected by clouds.

The basic principle behind all satellite-based surface irradiation retrievals is that the atmosphere affects the amount of radiation reaching the earth's surface. The most important factor in this equation, and the one that is most easily observable from space, is cloud cover. In the short wavelengths relevant for solar surface global and direct irradiation, clouds reflect and absorb radiation from the sun, reducing the amount of radiation reaching the surface and obscuring it from the satellite's view, while increasing the albedo of the point observed.

Already in 1982, Diak, Gautier, and Masse used an energy balance model to produce monthly maps of total surface global irradiation on a 12 x 12 km grid using data from the Geostationary Operational Environmental Satellites (GOES). The results were judged to be comparable to interpolated ground measurements. More than a decade later, Diak, Bland, and Mecikaski (1996) used the second generation of GOES to produce daily global irradiation values using a simple radiative transfer model and an albedo based cloud detection scheme.

Modern satellite retrievals compare several observations of the same location on the earth's surface under the assumption that at some point the pixel in question will have been observed under clear sky conditions. The observation with the lowest reflectance is assumed to be cloud-free, with higher reflectances being attributed to cloud cover (e.g. Diak, Bland, and Mecikaski (1996)). This basic retrieval principle can be expanded upon by assimilating additional data concerning the atmosphere, including but not limited to the elevation-based air mass (P. Ineichen and Perez 1999), atmospheric observations conducted by other sensors or satellites, satellite-derived cloud microphysical properties (Deneke, Feijt, and Roebeling 2008), ground-based measurements and circulation model outputs (Gupta et al. 2010).

Cloud cover alone, however, is not enough to compute solar irradiation at the earth's surface. Land cover also greatly affects the reflectance observed at a given location. Additionally, the observational geometry – sun height, the satellite's observation angle, etc. – affects the perceived brightness of a given point. These factors must be accounted for and, where necessary, corrected using observational data. Normalizing satellite counts based on solar geometry is relatively easy, as the positions of the sun, the earth and the satellite during each observation are known (Cano et al. 1986). Changes to the earth's surface reflectance, however, are more difficult to detect. Highly reflective areas, such as

deserts or regions covered in ice or snow, present special difficulties. Several algorithms exist to differentiate between snow and clouds by e.g. classifying pixels depending on their spectral characteristics beyond the visual light spectrum (Gesell 1989) or their temporal evolution (R. Posselt et al. 2012). Deserts continue to present problems due to their stable, high albedo.

After having detected the degree of cloud cover and any additional variables used by the algorithm, it is possible to compute the amount of solar irradiation at the earth's surface. Most algorithms employ two models for this step: one for clear skies and one for cloudy skies. The model outputs are varied – some produce only values concerning solar global irradiation, while others also account for direct irradiation. Some even produce spectrally resolved irradiation values (R. Mueller et al. 2012).

Although cloud albedo can be more easily computed than surface irradiation, most algorithms neglect this important climate variable. It can be computed by observing changes in pixel brightness over a period of time and examining the brightness offset compared to the minimum observed brightness (Hammer 2001). The cloud albedo can then be computed by normalizing the brightness counts according to the solar elevation, which has a daily and an annual cycle, and the sun-earth distance, which varies seasonally. Additional reflectance above the minimum observed brightness is considered a product of Lambertian reflection by clouds (R. Mueller, Trentmann, Stöckli, et al. 2011).

In principle, all of these retrieval techniques are possible using any satellite with the sensors in the visual light spectrum, whether the satellite orbits the poles or maintains a geosynchronous orbit. Both configurations have advantages and disadvantages. Polar orbiters generally have a higher spatial resolution due to their closer proximity to the earth, but they only observe a single swatch of the earth's surface at a time and it can take up to several weeks for a single satellite to return to observe the same location. This makes it difficult to reach a high level of accuracy, especially concerning cloud albedo and direct irradiation, in light of the high temporal variability of cloud cover, which has a strong influence on the three ECVs that are the focus of this study. Although geo synchronous satellites observe the earth from a much greater distance, they observe the same point on the earth's surface several times on the same day. Additionally, their resolution of down to one kilometer at nadir makes them well-suited for climate studies, which focus more on regional and global rather than local scales. One large drawback of working exclusively with geosynchronous satellites, however, is that due to their viewing geometry they cannot

observe the earth's poles. In order to obtain satellite observations of high latitudes, it is therefore necessary to use polar-orbiting satellites.

2.3.2. Data sets

There are only few data sets that provide information on cloud albedo. In contrast, there is an ever-growing number of satellite-derived data sets concerning surface solar irradiation. In the following section, the focus will be on data sets that come close to satisfying the requirements of this study.

NASA and the Global Energy and Water Cycle Experiment (GEWEX) have used data collected during in the International Satellite Cloud Climatology Project (ISCCP) to produce a Surface Radiation Budget (SRB) product, which provides solar global and direct irradiation values for the entire earth from 1993 to 2007 on a $1 \times 1^\circ$ grid. The data was created using a modified version of the method by Pinker and Laszlo (1992), which uses a radiative transfer model and modeled water vapor and temperature column values taken from the GEOS-4 model results, as well as model-derived aerosol climatologies, satellite observations of the ozone column and satellite observations of cloud cover to calculate downwelling solar global and direct irradiation. Although these data are conveniently available for the entire globe, they have a very low resolution. Also, the bias as compared to BSRN measurements is well above the target bias values set for this study (Stackhouse 2011).

The method used to produce the SRB product was later improved by (D. P. Kratz et al. 2012) and used in the Fast Longwave And Shortwave Radiative Fluxes (FLASHFlux) project to produce near real-time radiation data. FLASHFlux uses data collected by the Terra and Aqua satellites, as well as outputs produced by the GEOS 5 general circulation model. The FLASHFlux product utilizes the Langley Parameterized Shortwave Algorithm (Gupta et al. 2010) to produce data on global irradiation within a week of observation. Its aim is to provide near real-time irradiation data until more accurate irradiation data is available from the Clouds and the Earth's Radiant Energy System (CERES) sensor, which is published 6-12 months after the point of observation (Sawaengphotkhai 2009).

NASA's CERES product is derived from data collected on board polar orbiting satellites since 1998. It utilizes data observed by CERES, as well as model outputs and surface observational data to compute monthly surface fluxes and other variables on a 1° global grid (Wielicki et al. 1996). It is considered more accurate than the SRB and FLASHFlux

products, but only rarely meets the quality standards set for this study (David P. Kratz et al. 2010). Additionally, the spatiotemporal resolution is below this study's requirements.

The HelioClim databases contain data observed by the Meteosat Prime satellite (see chapter 3.1). They were produced using the Heliosat-2 method (Rigollier, LefÈvre, and Wald 2004), which is based on the Heliosat-1 method by Cano et al. (1986). They provide daily means of solar global surface irradiation from 1985-2005 from Meteosat observations, collected in reduced resolution (~20 km) during the ISCCP project (Lefèvre, Wald, and Diabaté 2007). Additionally, hourly averages of solar surface global irradiation are available from 2004 onwards with a resolution of approximately 10 km using the Heliosat-2 method (Rigollier, LefÈvre, and Wald 2004). The data covers the field of view of Meteosat Prime and the low-resolution version covering the time from 1985 to 2005 are available for free, with high-resolution, more current data available for a fee from the Solar Radiation Data (SoDa) platform (SoDa: Solar Radiation Data 2012).

The SolarGIS database contains 30 minute averages of surface solar global and direct irradiation observed at the Meteosat-Prime, Meteosat-IODC, GOES-East and GMS positions with a resolution of approximately 250 m. Meteosat-Prime coverage is available from 1994 to present, Meteosat-IODC and GOES-East data is available since 1999 and GMS coverage from 2005. The satellite observations are combined with gridded air temperature at 2 m height and water vapor data from NCEP, atmospheric optical depth calculated from data provided by ECMWF and snow depth data provided by NOAA (GeoModel Solar s.r.o. 2012b). The data validates well compared with other commercial data sets (Pierre Ineichen 2011), but is only available for very high prices (GeoModel Solar s.r.o. 2012a).

(Zhang et al. 2004) have used ISCCP data collected from all geosynchronous satellites in combination with NASA's Goddard Institute for Space Studies (GISS) radiative transfer model (Bishop, Rossow, and Dutton 1997) and additional ancillary data to produce a data set of surface global irradiation spanning the years 1983 to 2001. The data is available in three hourly time steps with a resolution of 280 km. The data set is long enough for use in climate studies, but with a much too low resolution and few possibilities to extend its coverage into the future.

The CM-SAF CCloud And Radiation project (CLARA) provides daily averages of surface solar global irradiation data for the entire world using AVHRR observations collected on polar orbiting satellite platforms for the entire globe from 1989 to 2009 on a $0.25^\circ \times 0.25^\circ$

grid (Trentmann, Müller, et al. 2012a). It incorporates ancillary data from the ERA-Interim data set, aerosol information from the GADS/OPAC data base and surface albedo from the SARB/CERES project. The methodology outlined in (R. W. Mueller et al. 2009) is used to compute global irradiation. The CLARA data set validates quite well (Trentmann, Müller, et al. 2012b), but it provides only data concerning one of the three CDRs focused on in this study at relatively low resolution.

The data that most closely matches the goals of this study are the CM SAF Meteosat (MVIRI) Solar Surface Irradiance and Effective Cloud Albedo Climate Data Sets. They provide all three of the target variables for the Meteosat full disk in Meteosat First Generation native resolution ($0.03^\circ \times 0.03^\circ$) as hourly means from 1983 until the introduction of Meteosat Second Generation in 2005 (Trentmann, Träger-Chatterjee, et al. 2012) with the method described in (R. W. Mueller et al. 2009), which requires only observations from the visual channel and readily available water vapor, ozone and aerosol climatologies. This data set is being continually extended using current data from Meteosat Second Generation satellites (Trentmann et al. 2010). These data have been validated to have the highest accuracy among other publicly available, global data sets (R. Posselt et al. 2012). In light of the availability of all three goal variables, the data's high accuracy and resolution, and the presence of a long time series, these data fulfill the requirements for the current study, but only for the field of view of the Meteosat First Generation satellites. Due to MAGICSOL's low data requirements and its self-calibration mechanism, it should be possible to apply it to observations from sensors on board other satellite platforms (e.g. GOES and GMS) (R. Posselt, Müller, Trentmann, et al. 2011). The plausibility of extending these data to the other satellites in the geostationary ring will be the focus of this thesis' empirical work.

3. Data

As is shown in chapter 2, few data sets are available containing data on cloud albedo. Among the many available data sets concerning surface solar global and direct irradiation, none fulfill all criteria outlined in chapter 1: open availability, high resolution, long-term availability and high accuracy.

In the following sections, the data used in this study in order to fill these gaps will be introduced.

3.1. Satellite data

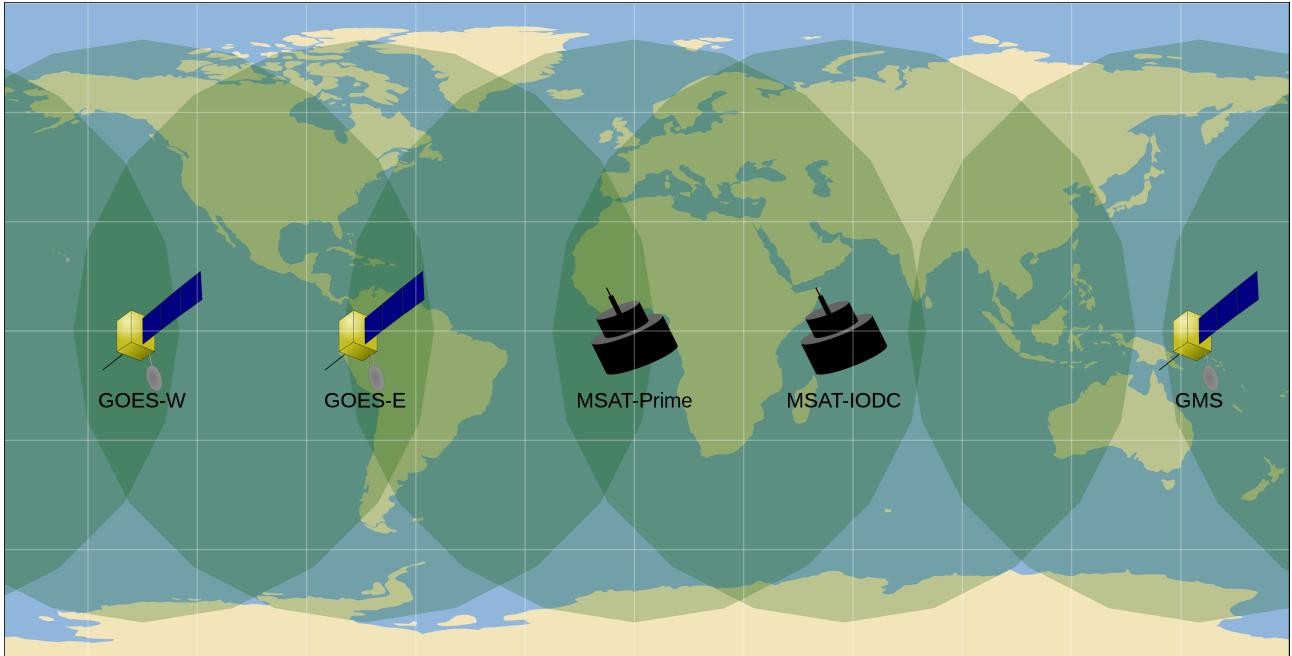

Figure 3.1: Satellite spatial coverage and satellite positions. Based on: (NOAA US Department of Commerce 2012a; EUMETSAT 2012).

Geosynchronous satellite coverage has been available for certain parts of the world since the 1970s. By 1998, coverage of the Indian Ocean was added, closing the last spatial gaps in geosynchronous satellite coverage. The geosynchronous satellites have been swapped out frequently, but attempts have been made to occupy the same positions consistently, providing comparable observations over a long period of time (see figure 3.1).

Because the focus of this study is to test the feasibility of a global CDR data set, not all of the available data is relevant. During long periods of time, the GOES satellites switched frequently between the GOES-W and the GOES-E positions, causing difficulties with the data and making these periods less useful for our current goal. Before 1998, the Meteosat IODC (Indian Ocean Data Coverage) position was not occupied, meaning that it would be better to use data from after this date. Also, acquiring data from the JMA has proven difficult, so that a time frame was desirable where coverage from the GMS position was provided by either EUMETSAT or NOAA.

From 4/23/2003 – 7/13/2004, normal coverage was provided at the GOES-W and GOES-E positions by GOES-10 and GOES-12, respectively, and due to technical problems with JMA's GMS-5 satellite, the decommissioned GOES-9 satellite was recommissioned to provide temporary on-site service from the GMS position until the next JMA satellite, MTSAT, was launched (Morris 2012). At the same time, normal Meteosat coverage by

EUMETSAT was provided by Meteosat-7 at the Meteosat Prime position and Meteosat-5 at the Meteosat IODC position (EUMETSAT 2012). This provided full geosynchronous coverage of the entire planet, excepting the poles, with all data readily available from EUMETSAT and NOAA. One month, June 2003, was chosen from this period for use in the current study.

For a more detailed description of when each position was occupied by what satellite, see table 3.1.

Table 3.1: Temporal coverage for each satellite position. Data that are unavailable for this study are shown in gray: GMS due to data acquisition difficulties, GOES-6 and 7 because of difficulties associated with their variable positions, and Meteosat Second Generation because it is currently being used to produce the ECVs of this study using another method and is therefore not relevant for the study's goal of producing data from archival observations. Sources: (EUMETSAT 2012; NOAA US Department of Commerce 2012a; Japanese Meteorological Agency 2012).

Year	GOES-W (-135°)	GOES-E (-74°)	MSAT-Prime (0°)	MSAT-IODC (57.5°)	GMS (155°)
1978 – 1980	GOES-2	SMS-1 SMS-2+	Meteosat-1		GMS
	GOES-3				
1981 – 1985	GOES-4	GOES-5	Meteosat-2		GMS-2
	Variable – GOES-6 & GOES-7				
1986 – 1990		Variable – GOES-6 & GOES-7	Meteosat-3 Meteosat-4		GMS-3
1991 – 1995	GOES-9	GOES-8	Meteosat-5		GMS-4
1996 – 2000	GOES-10	GOES-12	Meteosat-6		GMS-5
2001 – 2005	GOES-11	GOES-13	Meteosat-7	Meteosat-5	GOES-9++
2006 – 2010	GOES-15	Meteosat Second Generation	Meteosat-7		MTSAT
2011 – 2012					

Although the GOES and Meteosat satellite series can be considered to be quite similar,

some differences should be noted. The Meteosat Visible and InfraRed Imager (M VIRI) instrument on board the Meteosat platform scans with a ground resolution of 2.5 km at nadir, whereas the GOES imager has a nadir resolution of 1 km and GMS a resolution of 1.25 km. The imagers' visual channels also have different response spectra – Meteosat's visual band observes electromagnetic radiation with wavelengths from 0.5 – 0.9 μ m, while GOES observes from 0.5 – 0.7 μ m. The GMS visual band is similar to that of Meteosat, extending from 0.55 – 0.9 μ m (NOAA US Department of Commerce 2003). The extent to which this affects the accuracy of the algorithm used in this study will be evaluated during the validation process (see chapter 4.3).

Because June of 2003 was used, no GMS data was obtained for this study. Raw data for processing was obtained for the GOES-W, GOES-E and GMS positions directly from the NOAA Comprehensive Large Array-data Stewardship System (CLASS) archive in the netCDF format (NOAA US Department of Commerce 2012b). Preprocessed data containing the surface solar global and direct irradiation, as well as cloud albedo, for the Meteosat Prime position was provided by the EUMETSAT Satellite Application Facility on Climate Monitoring in the netCDF format (EUMETSAT Satellite Application Facility on Climate Monitoring 2012) and for the Meteosat-IODC position by the PVGIS project as a GRASS GIS database (European Union 2012). The total amount of data collected amounted to 4 terabytes.

3.2. *Climatologies*

The MAGIC SOL method, which was used in this study to compute the goal CDRs, uses aerosol, water vapor and ozone climatologies in addition to satellite observations as atmospheric inputs for its radiative transfer model (RTM) (R. Mueller, Trentmann, Stöckli, et al. 2011).

The aerosol climatologies are based on medians from the AeroCom model and AERONET ground measurements on a 1x1° grid (Kinne et al. 2006). These climatologies validate quite well in comparison with similar data sets, such as those offered by NCEP, when evaluating surface solar global irradiation. This is particularly true for areas with few measurements, which are of especially interesting in light of this study's goals (Pierre Ineichen 2010).

Water vapor climatologies were taken from the global reanalysis data set by ECMWF (ERA-40 for years before 1989 (Uppala et al. 2005) and ERA-Interim from 1989 onwards

(Berrisford et al. 2009)). In order to reduce the amount of input data required, monthly values of the total water vapor column were interpolated onto a 0.5x0.5° grid (R. Mueller, Trentmann, Träger-Chatterjee, et al. 2011).

The ozone input into the RTM was based on the ozone content of the standard atmosphere by Krämer et al. (2003).

3.3. Validation data

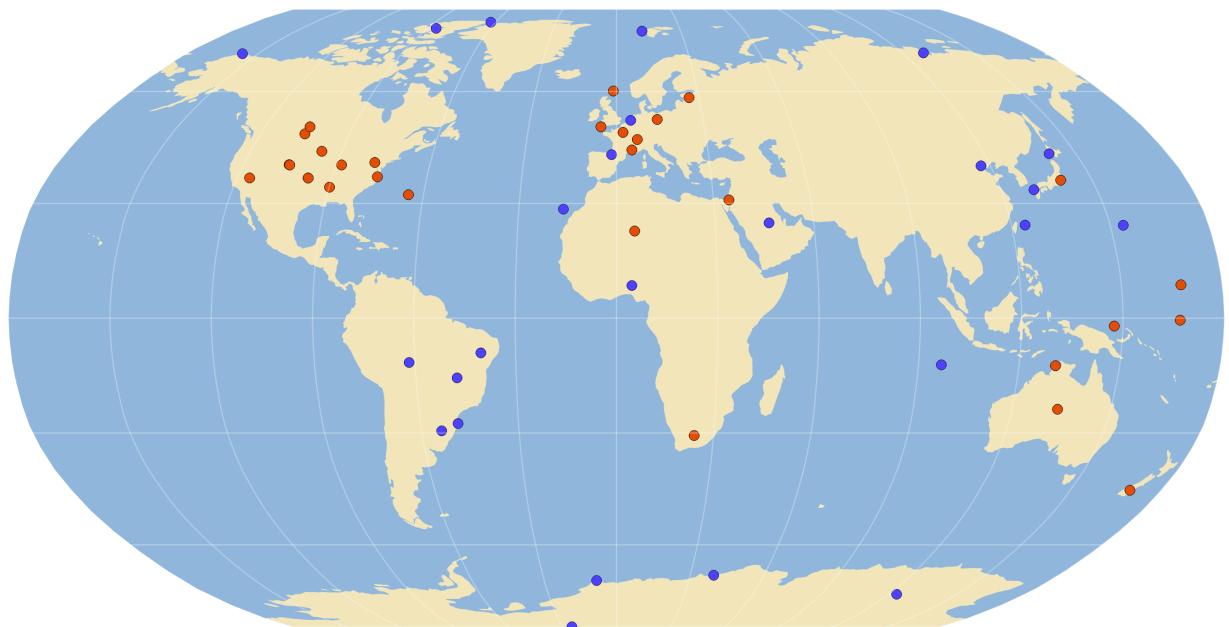

Figure 3.2: BSRN stations. Stations that registered measurements during the time period of this study are in red, other stations without reported data for June 2003 or that were outside the used satellites' fields of view are in blue. Based on: (Ohmura et al. 1998).

The BSRN has 56 stations, 35 of which were delivering data during this study's time frame and 30 of those were within the field of view of the satellites used (see figure 3.2 and table 3.2). The network was chosen as the source of ground truth data despite its low number of stations due to their global distribution and the fact that the data they collect contains both surface solar global and direct irradiation (World Radiation Monitoring Center – Baseline Surface Radiation Network 2012b). For more information about the BSRN stations and what variables they measure, see chapter 2.1.2.

Additional, comparable SIS data was obtained from the ERA-Interim archive (Dee et al. 2011) and the CLARA surface radiation product from CM SAF (Trentmann, Müller, et al. 2012a). Unfortunately, these data sources did not provide SID and CAL.

Qualitative validation data was obtained from the MODIS cloud fraction product (National

Aeronautics and Space Administration 2012). The cloud fraction product utilizes several spectral bands that are observed using the MODIS instrument, as well as a comprehensive suite of ancillary data on land cover, topography, solar geometry, and surface temperature to assess the degree of cloudiness in an observed pixel. The final product is composed of 1 km pixels, whose values are the percentage of 250 m pixels contained in each 1 km window that are identified with a high degree of confidence as being cloudy (Ackerman et al. 2010). Although the MODIS instrument is available on board both the Terra and the Aqua polar orbiting satellites, only data collected on the Aqua satellite was utilized in this paper. This is due to the fact that Aqua's orbit is on a sun-synchronous ascending node which observes at 13:30 local solar time, whereas Terra observes on a 10:30 descending node (Maccherone 2012). The noontime observations were assumed to contain higher contrast, making it easier to qualitatively compare the cloud fraction product with the CAL data produced in the course of this study. For each satellite, an observation near local noon was used from the 1st, 15th and 30th day of the month tested.

Table 3.2: Relevant BSRN station names, positions and elevations. Based on: (World Radiation Monitoring Center – Baseline Surface Radiation Network 2012a).

Station Name	Position (°N, °E)	Elevation (a.s.l.)
Alice Springs	-23.8°, 133.9°	547 m
Bermuda	32.3°, -64.7°	8 m
Billings	36.6°, -97.5°	317 m
Bondville	40.1°, -88.37°	1689 m
Boulder	40.1°, -105.2°	1689 m
Boulder	40.1°, -105.0°	1577 m
Camborne	50.2°, -5.3°	88 m
Carpentras	44.1°, 5.1°	100 m
Chesapeake Light	36.9°, -75.7°	37 m
De Aar	-30.7°, 24.0°	1287 m
Darwin	-12.4°, 130.9°	30 m
Desert Rock	36.6°, -116.0°	1007 m
S. Great Plains	36.6°, -97.5°	318 m
Fort Peck	48.3°, -105.1°	634 m
Goodwin Creek	34.3°, -89.9°	98 m
Kwajalein	8.7°, 167.7°	10 m
Lauder	-45.0°, 169.7°	350 m
Lerwick	60.1°, -1.2°	84 m
Lindenberg	52.2°, 14.1°	125 m
Momote	-2.1°, 147.4°	6 m
Nauru Island	-0.5°, 166.9°	7 m
Palaiseau, SIRTA Observatory	48.7°, 2.2°	156 m
Payerne	46.8°, 6.9°	491 m
Rock Springs	40.7°, -77.9°	376 m
Regina	50.2°, -104.7°	578 m
Sede Boger	30.9°, 34.8°	500 m
Sioux Falls	43.7°, -96.6°	473 m
Tamanrasset	22.8°, 5.5°	1385 m
Tateno	36.1°, 140.1°	25 m
Toravere	58.3°, 26.5°	70 m

4. Methods

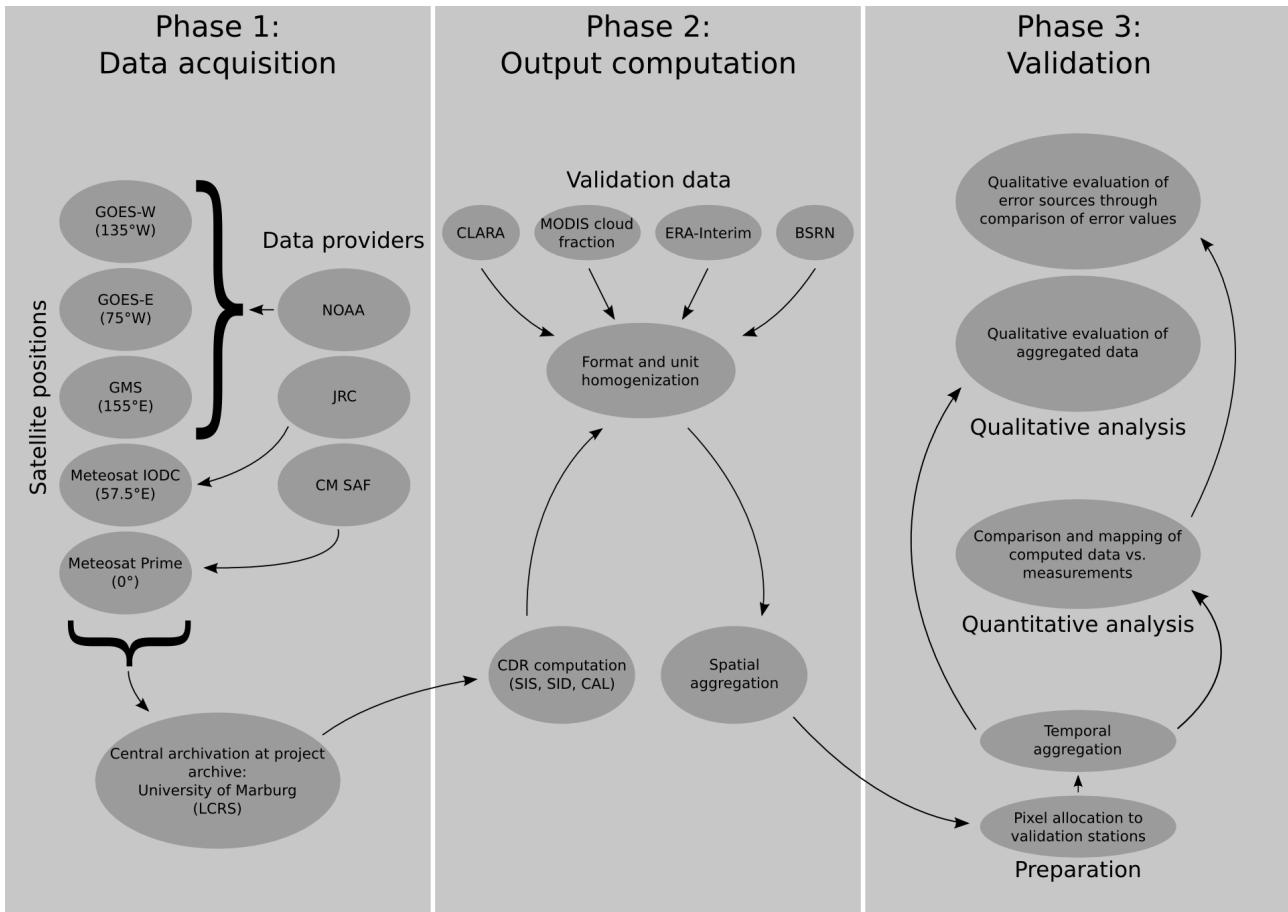

Figure 4.1: Workflow diagram of the three phases of the empirical investigation.

The empirical portion of this thesis was performed in three phases: (i) data acquisition, (ii) output computation and (iii) validation (see figure 4.1). In phase (i), data concerning each satellite was collected and archived from the data providers. In phase (ii), the CDRs were computed for all GOES satellites. After that, the produced data, as well as the validation data, was reformatted into a single format and the units converted, if needed, to Wh / m². Finally, a map combining each globally available time step was created by merging the relevant scans of each satellite processed. Phase (iii) began with the temporal aggregation of all computed and measured data to create a temporally homogeneous basis of comparison. Afterwards, the computed data was qualitatively validated and quantitatively compared with the validation data at various temporal aggregation levels.

4.1. Data acquisition

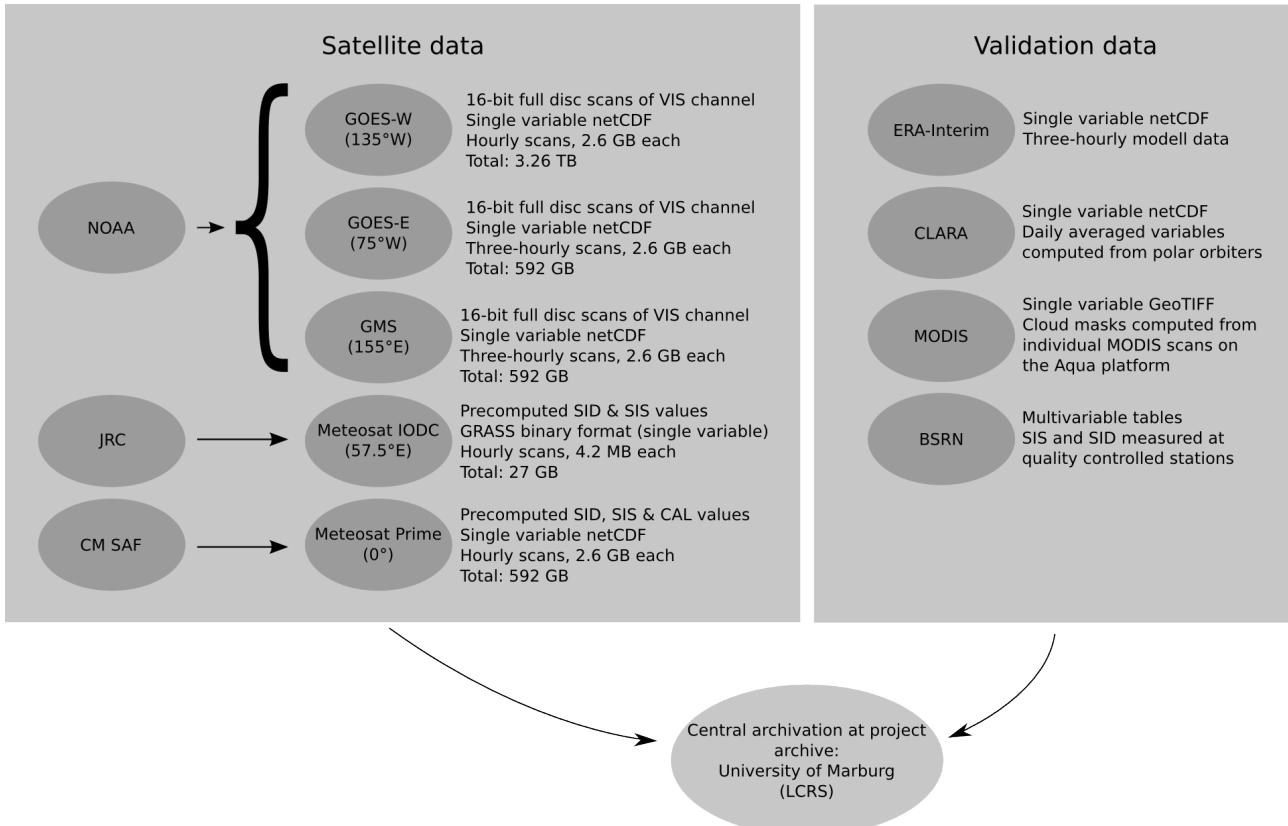

Figure 4.2: Workflow diagram of phase i: data acquisition.

As a first step, all data was acquired and centrally archived (see figure 4.2). Due to the large amount of data, this was accomplished using scripts.

Data from the three GOES satellites that were used was ordered and downloaded from NOAA's Comprehensive Large Array-data Stewardship System (CLASS) (NOAA US Department of Commerce 2012b). The data was available in netCDF format with 16 bits per pixel, so that each full disc scan file required 2.6 GB disk space. Because only 100 scans could be ordered simultaneously, several orders were placed at once. GOES-9++ performed full disc scans each hour and sometimes even more frequently, requiring 836 downloads totaling 2.1 TB disc space. GOES-10 scanned every three hours and, when needed, every half hour, requiring 236 downloads for a total of 592 GB. GOES-12 also scanned every three hours, requiring 243 downloads for a total of 592 GB. In total, the GOES data amounted to 3.26 TB.

Because CLASS products are only available for 120 hours after ordering, several orders had to be repeated. Downloads were conducted over more than four weeks using a download accelerator, Aria2, which opens multiple connections to a host and splits files

into chunks that are then downloaded in parallel (Tsujikawa 2012). This made it possible to download the data within the project time frame.

The necessary CDRs for the Meteosat-Prime coverage area were already available directly from CM SAF. They were ordered and downloaded from the CM SAF web user interface as netCDF files and required a total of 27 GB disk space (EUMETSAT Satellite Application Facility on Climate Monitoring 2012).

The PVGIS project at the JRC had also used the MAGICSOL method to create data sets of SIS and SID. At the author's request, the preliminary, unpublished results were made available as a GRASS GIS database with a disk size of 6 GB (Huld 2012).

Validation data from BSRN was made available directly through the project's FTP server (World Radiation Monitoring Center – Baseline Surface Radiation Network 2012c). The files were stored as station-to-archive files and were converted into comma separated value tables using the BSRN toolbox (Sieger 2012). ERA-Interim downwelling surface irradiation data was downloaded from the ECMWF server (European Centre for Medium-Range Weather Forecasts 2012). SIS data computed from AVHRR was downloaded from the CM SAF Web User Interface (EUMETSAT Satellite Application Facility on Climate Monitoring 2012). MODIS cloud masks were ordered from the LAADS platform (National Aeronautics and Space Administration 2012). Before they were downloaded, they were georeferenced and converted into the GeoTIFF format by the server.

4.2. Output computation

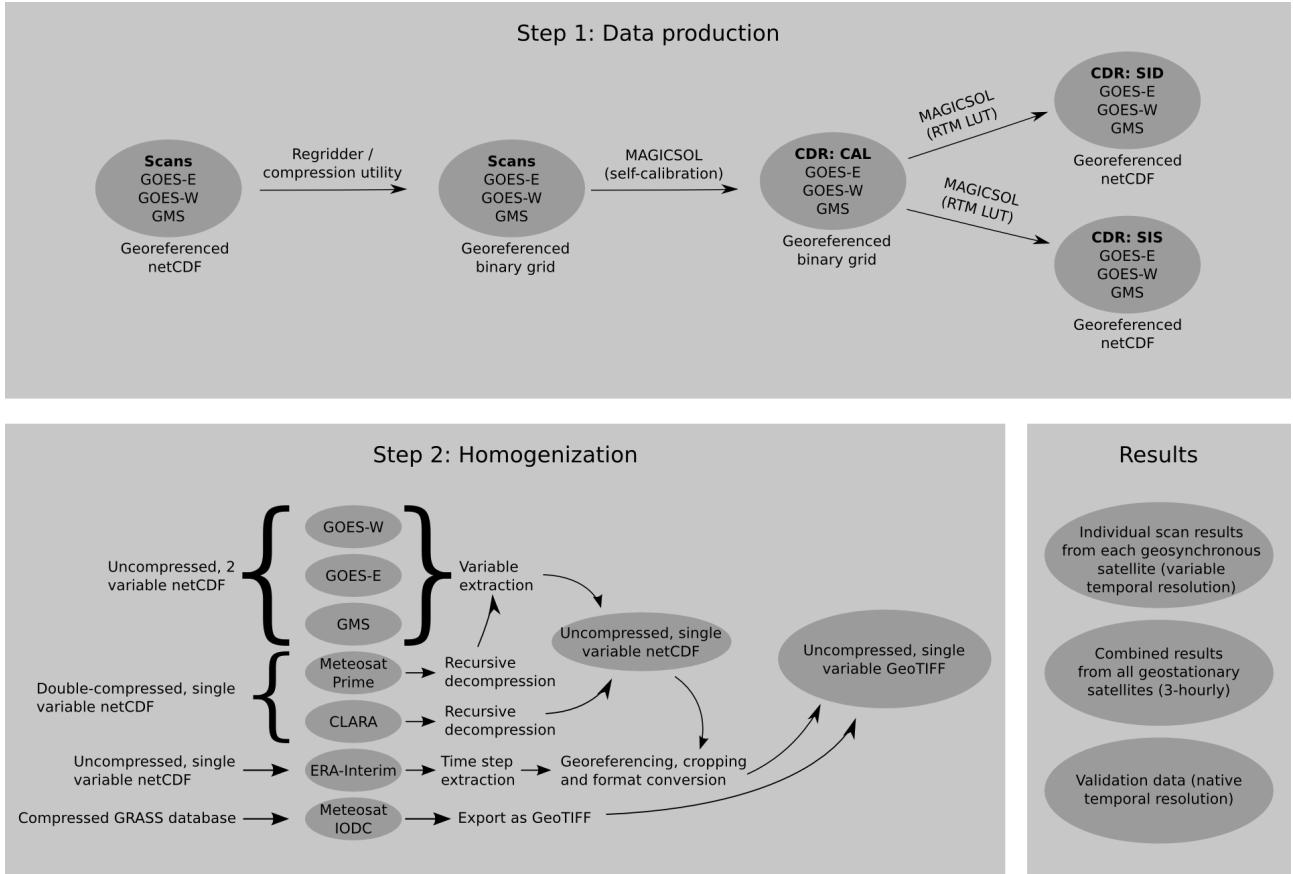

Figure 4.3: Workflow diagram of phase ii: output computation.

Several steps were necessary in order to convert the raw data from the satellites into CDRs. First, the data was preprocessed and outputs were computed. Then the produced data, as well as the validation data, were converted into a single format to facilitate inter-comparison. Finally, several additional, aggregated outputs were produced in order to make it possible to qualitatively evaluate the agreement between satellites, as well as their ability to detect global-scale phenomena (see figure 4.3).

In the first step, the scan data received from NOAA for the GOES-E, GOES-W and GMS positions was preprocessed using a regridding and compression utility (Müller 2012). This was done in order to convert the netCDF files provided by NOAA into a binary format which could be directly used by the MAGICSL software. The result was a collection of scans from each of the aforementioned satellites, converted into the binary XPIF format, reduced to 8-bit precision and warped onto a regular lat-lon grid with a horizontal resolution of 0.02° (approximately 2 km at the equator).

After the data was regridded, it was used to calculate the cloud albedo for each time step. This was done using the MAGICSL algorithm, which is based on the Heliosat algorithm

(Cano et al. 1986). The following section briefly explains the MAGICSOL method. The complete details can be found in R. Mueller, Trentmann, Träger-Chatterjee, et al. (2011).

First, the satellite counts observed at each pixel were normalized to correct for differences in illumination effects resulting from the satellite's viewing angle and the solar geometry relative to the earth at the observed point. Then the clear-sky reflectance (ρ_{cs}) for each pixel and time slot was computed by comparing each pixel observation over the course of seven days. The minimum reflectance for those seven days was assumed to correspond to a clear-sky observation of the ground at the pixel in question. This allowed for changes in ground cover that affect the pixel's albedo to be detected and compensated for in the course of the month.

The maximal reflectance for the current state of the satellite's radiometer at the time of the observation was computed by observing a target region with a high number of compact clouds. As each satellite had a large ocean region in its field of view, which provided a well-suited window for observing compact cloud decks, the "Roaring Forties" between 40°S and 50°S served as a target area. For each satellite, the 95th percentile of normalized counts in the near-noontime slot in this area was used to find the highest observable reflectance (ρ_{max}) for the satellite in question. Using the 95th percentile rather than the absolute maximum created more stable maximum values, as especially high observations resulting from sensor saturation were excluded. Subsequently, the effective cloud albedo (CAL) was computed for each observation of each pixel using the following formula:

$$CAL = \frac{\rho - \rho_{cs}}{\rho_{max} - \rho_{cs}} \quad (1)$$

Additionally, a snow test was applied to distinguish between albedo changes caused by cloud and snowfall, as outlined in Rebekka Posselt et al. (2011). This test assumes that consistently high pixel albedo indicates snow cover, whereas variably high albedo values can more readily be attributed to clouds. If snow is detected, ρ_{cs} is artificially raised for the pixel in question to compensate for the snow's high albedo.

Both the surface incoming shortwave radiation (SIS) and surface incoming direct radiation (SID) were then computed using the climatologies described in chapter 3.2 and the cloud albedo as inputs for an eigenvector-based look-up-table (LUT) approach (R. W. Mueller et al. 2009). This method interpolates between precomputed results of radiative transfer model runs, which were previously calculated using the libRadtran RTM (Mayer and

Kylling 2005).

After producing the data, it was necessary to convert it into a common format (see figure 4.3). This had the purpose of facilitating data intercomparison for the validation process.

The data that was produced in step 1 was written on a georeferenced, regular lat-lon grid with both SIS and SID contained as variables for each pixel in a single file for one time slot. The individual variables were extracted for each time slot into individual netCDF files, which were then cropped into the respective satellite viewing areas and converted into GeoTIFFs. Each raster contained a single variable (SIS or SID) for the satellite's viewing domain during a single scan.

The data collected by Meteosat-Prime was archived as single netCDF files containing both SIS and SID for each time step. The netCDF files were gunzipped inside tar archives. First, the files were untarred and decompressed, after which each variable was extracted into a separate netCDF file. From there, the netCDFs were converted into GeoTIFFs, as was done with the GOES data.

The Meteosat-IODC coverage data was delivered as a compressed GRASS GIS database. This database was decompressed and imported into the local GRASS GIS database on the data server used for archiving the study's data. Following that, each time step for SIS and SID, respectively, was simultaneously cropped and exported from the database as a GeoTIFF.

The CLARA daily SIS data was provided in the same format as the Meteosat-Prime data. Because no SID data was provided, the files were recursively decompressed and converted into GeoTIFFs directly.

The ERA-Interim data was downloaded as a single, uncompressed netCDF file containing SIS for each computed time step in the data set. Each time step was extracted and converted into a GeoTIFF. The data was then reprojected from its native coordinate system into the coordinate system shared by the other data sources.

The results were GeoTIFFs from each data source, referenced onto a regular lat-lon coordinate grid in the temporal resolution the data was provided in. Additionally, global data was synthesized from the satellite scans on the lowest common temporal scale (three hours).

4.3. Validation

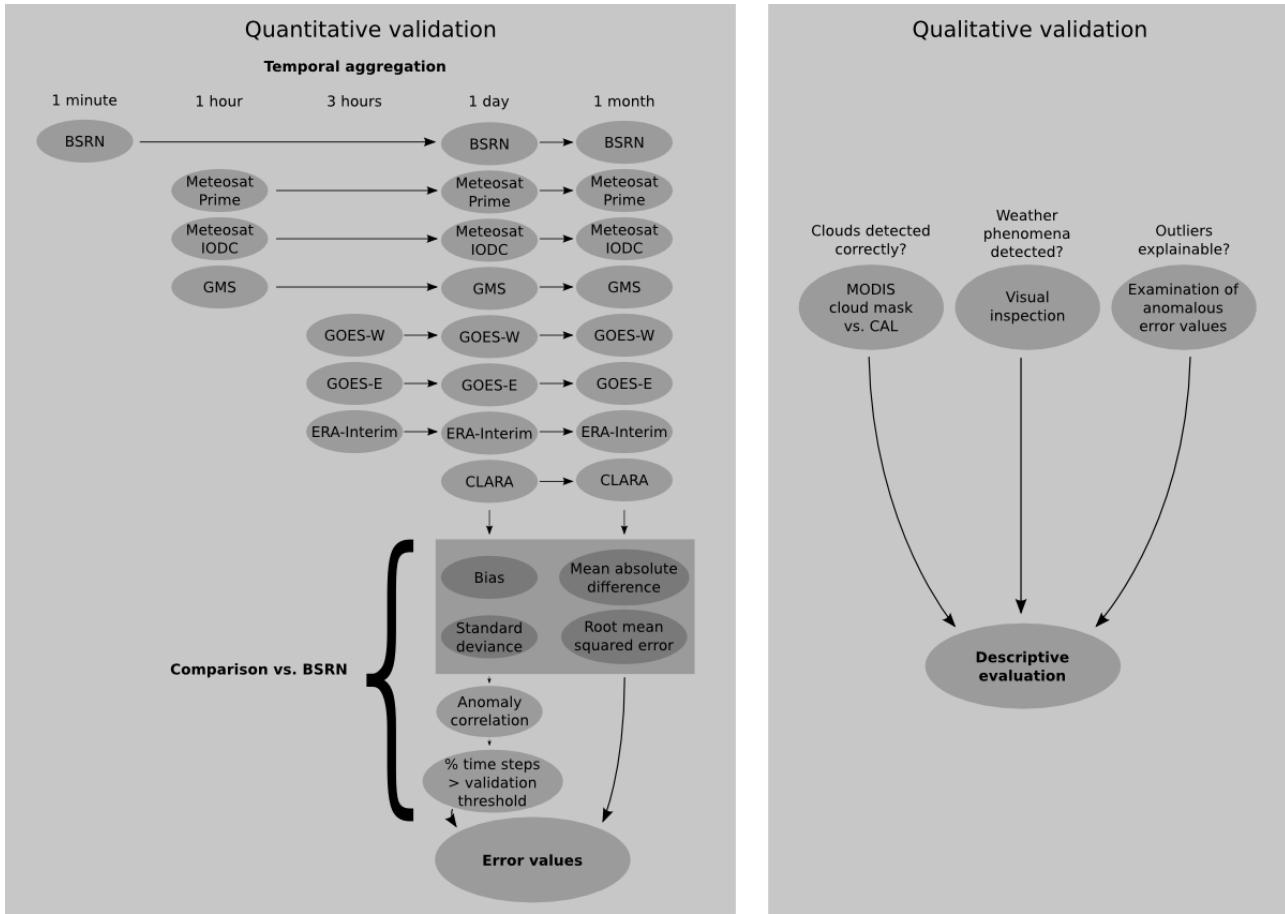

Figure 4.4: Workflow diagram of phase iii: validation.

In the third phase, the produced data was evaluated both qualitatively and quantitatively. For an overview of both validation processes, see figure 4.4.

The quantitative validation was performed by comparing the data produced with the accuracy of the ERA-Interim and CLARA data under the assumption that the BSRN station data was correct. Because no validation measurements for effective cloud albedo (CAL) were available, only surface incoming direct radiation (SID) and surface incoming shortwave radiation (SIS) were validated numerically.

To provide a comparable basis of comparison for all data sets, the data were first temporally aggregated to a common resolution. The BSRN data was available as minute-by-minute measurements, whereas the Meteosat-Prime, Meteosat-IODC and GMS scans were available hourly. GOES-W and GOES-E, as well as the ERA-Interim validation data, were only available in three-hourly resolution, and the CLARA data was available only on a daily basis. Thus the SIS and SID values were first aggregated to daily sums of Wh / m². Additionally, they were aggregated to monthly sums in order to compare the accuracy of

each data set per station of the course of the entire month. Because the ERA-Interim and CLARA data contained only SIS data, the SID data produced using MAGICSOL was compared only with the BSRN measurements.

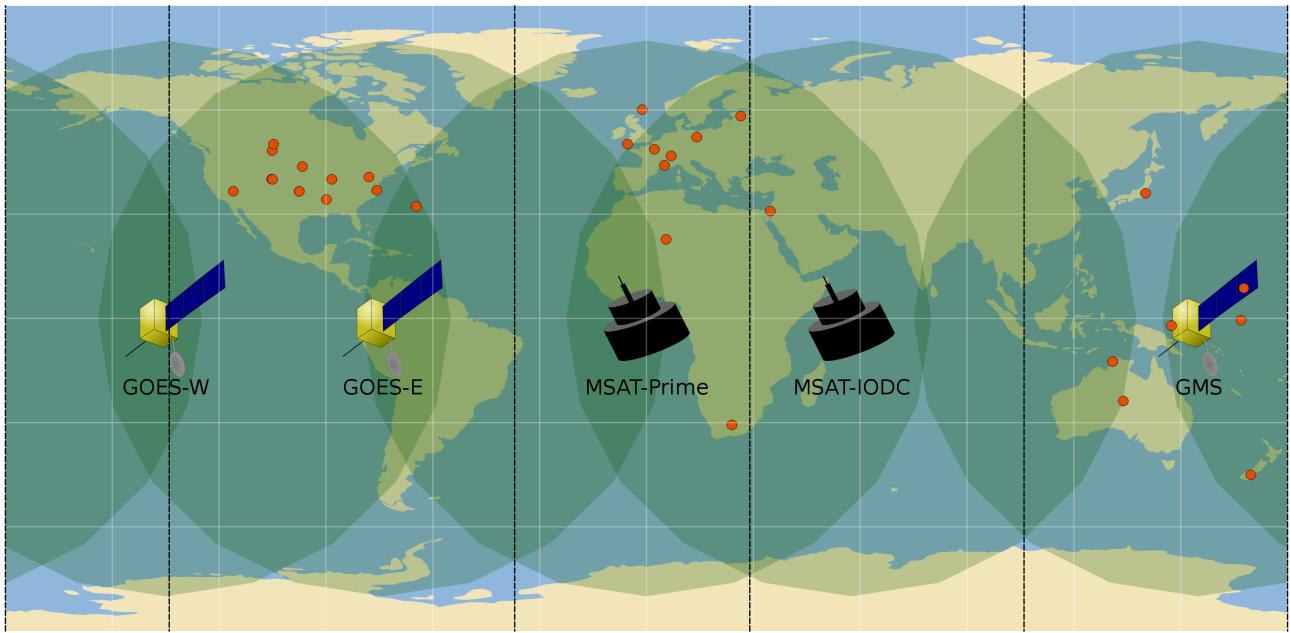

Figure 4.5: Satellite viewing areas. Individual satellites are shown on the map. The ellipses beneath them denote the satellite's viewing geometry. Black dotted lines denote borders between satellite domains used in this study, points are BSRN stations used for validation. Based in part on: (NOAA US Department of Commerce 2012a; EUMETSAT 2012; Ohmura et al. 1998).

After aggregating the data, the values in the data set was extracted at the position of the validation stations for each time step. For an overview of the stations used and the satellites they were assigned to, see figure 4.5.

Each data set was evaluated based on the following error values, according to Wilks (2005) and R. Posselt, Müller, Trentmann, et al. (2011). In each equation, y stands for a predicted value, o for the corresponding value measured at the BSRN station, k for a given sample at a point in time and n the total number of samples.

$$Bias = \frac{1}{n} \sum_{k=1}^n (y_k - o_k) \quad (2)$$

The bias, or mean error, shows the mean difference between two data sets. A negative bias indicates that the predicted values are generally lower than the observed data, whereas a positive bias reflects an overestimation compared with the observed data. One weakness of this value is that positive and negative differences between the observed and

predicted data effectively cancel each other out.

$$MAD = \frac{1}{n} \sum_{k=1}^n |y_k - o_k| \quad (3)$$

The mean absolute difference (MAD) is computed similarly to the bias, but the magnitude of the difference between the two data sets, rather than its direction, is evaluated. MAD is a more general value for how much one data set deviates from another, independent of the deviation's direction.

$$SD = \sqrt{\frac{1}{n-1} \sum_{k=1}^n ((y_k - o_k) - (\bar{y}_k - \bar{o}_k))^2} \quad (4)$$

The standard deviance (SD) measures the variability of the deviance between two data sets.

$$AC = \frac{\sum_{k=1}^n (y_k - \bar{y})(o_k - \bar{o})}{\sqrt{\sum_{k=1}^n (y_k - \bar{y})^2} \sqrt{\sum_{k=1}^n (o_k - \bar{o})^2}} \quad (5)$$

The anomaly correlation (AC) shows how much a given sample deviates from the monthly mean of all samples in that data set. It shows to what extent deviations from each data set's mean are reflected in the other data set, making it possible to see whether similar phenomena are observed in two data sets, independent of any systematic bias contained in either one. Because only one month of data was computed, the AC was only computed for the daily data as and not for the monthly mean.

$$RMSE = \sqrt{\frac{1}{n} \sum_{k=1}^n (y_k - o_k)^2} \quad (6)$$

The root mean squared error (RMSE) is a measure for the magnitude of differences between two data sets, similar to the MAD. However, because the values measured are squared, RMSE is more sensitive to outliers.

$$Fraction\ above\ threshold = \frac{t}{n} \quad (7)$$

The fraction of time steps above the validation threshold is a measure of the proportion of the generated data whose accuracy is lower than the target accuracy. In this case, t denotes the number of samples whose deviation from the BSRN samples is higher than the target deviation. The thresholds for each variable and time step can be found in 1.1.

The qualitative validation was performed by examining various aspects of the data manually. First, MODIS cloud masks were compared with the cloud albedo values generated by the MAGICSOL software. It was assumed that if the algorithm had performed well, the cloud mask would correspond with high cloud albedo values generated by MAGICSOL.

Additionally, the scans from each individual satellite were merged into a single, global image. Because the highest temporal resolution was three-hourly, one image was made for every three hours. Where possible, scans beginning simultaneously were combined. When this was not possible, the scan beginning closest to the other scans was used. The largest difference between scan start times for combined imagery was 25 minutes, ensuring the most simultaneous unified geosynchronous scan possible (see table 4.1). Because CAL was not available for Meteosat-IODC coverage, global images were only created for SIS and SID.

Table 4.1: Scan times that were used to create combined, global imagery.

Satellite / Time slot (UTC +0)	0000	0300	0600	0900	1200	1500	1800	2100
GOES-W	0000	0300	0600	0900	1200	1500	1800	2100
GOES-E	2345	0245	0545	0845	1145	1445	1745	2045
Meteosat Prime	0000	0300	0600	0900	1200	1500	1800	2100
Meteosat IODC	0000	0300	0600	0900	1200	1500	1800	2100
GMS	0025	0325	0625	0925	1225	1525	1825	2125

These pictures were examined in order to determine whether phenomena could be observed across several satellites and to qualitatively evaluate the plausibility of the generated values. Of the 240 3-hourly time steps in the study period, 16 scans were missing. These time steps were not used to make global images.

Cross-satellite agreement was also tested by examining the deviance in generated values

of pixels in areas where two satellites' viewing areas overlapped.

5. Results and discussion

In the following chapter, the results are introduced and discussed in detail.

5.1. *Regridding*

The first step in the data production process was to regrid each satellite scan onto a regular lat-lon grid in a format readable by the MAGICSOL software (see figure 4.3). The results can be seen in figures 5.1, 5.2 and 5.3.

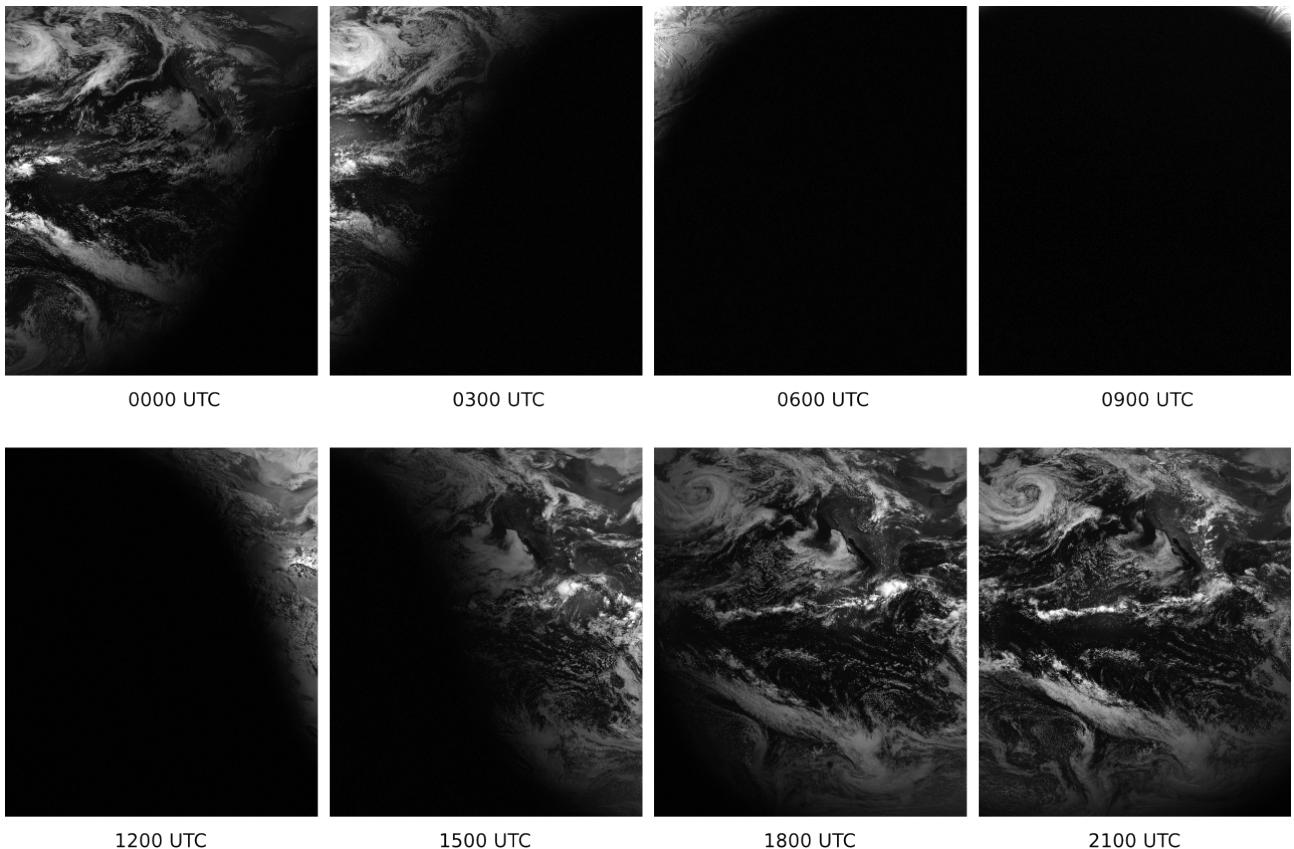

Figure 5.1: Regridded normalized scans performed by GOES-10 (GOES-W) on a typical day (152).

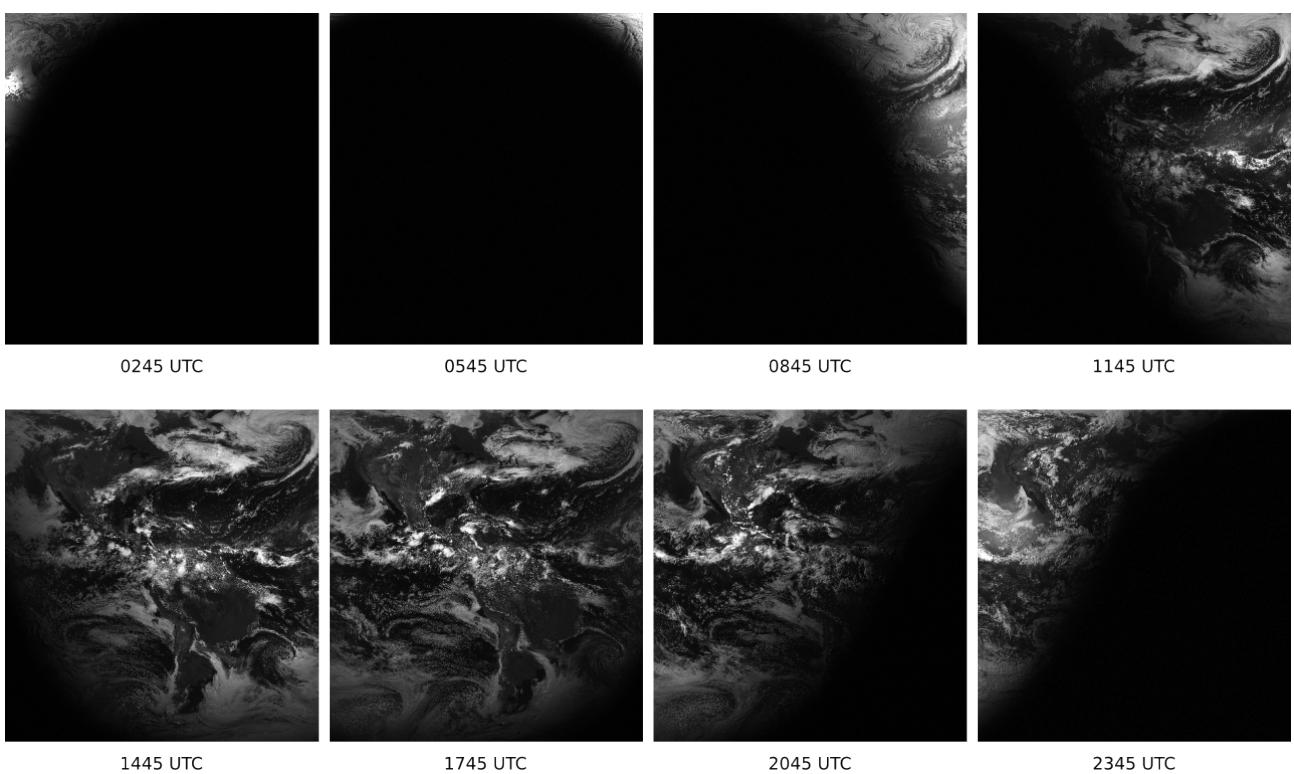

Figure 5.2: Regridded normalized scans performed by GOES-12 (GOES-E) on a typical day (166).

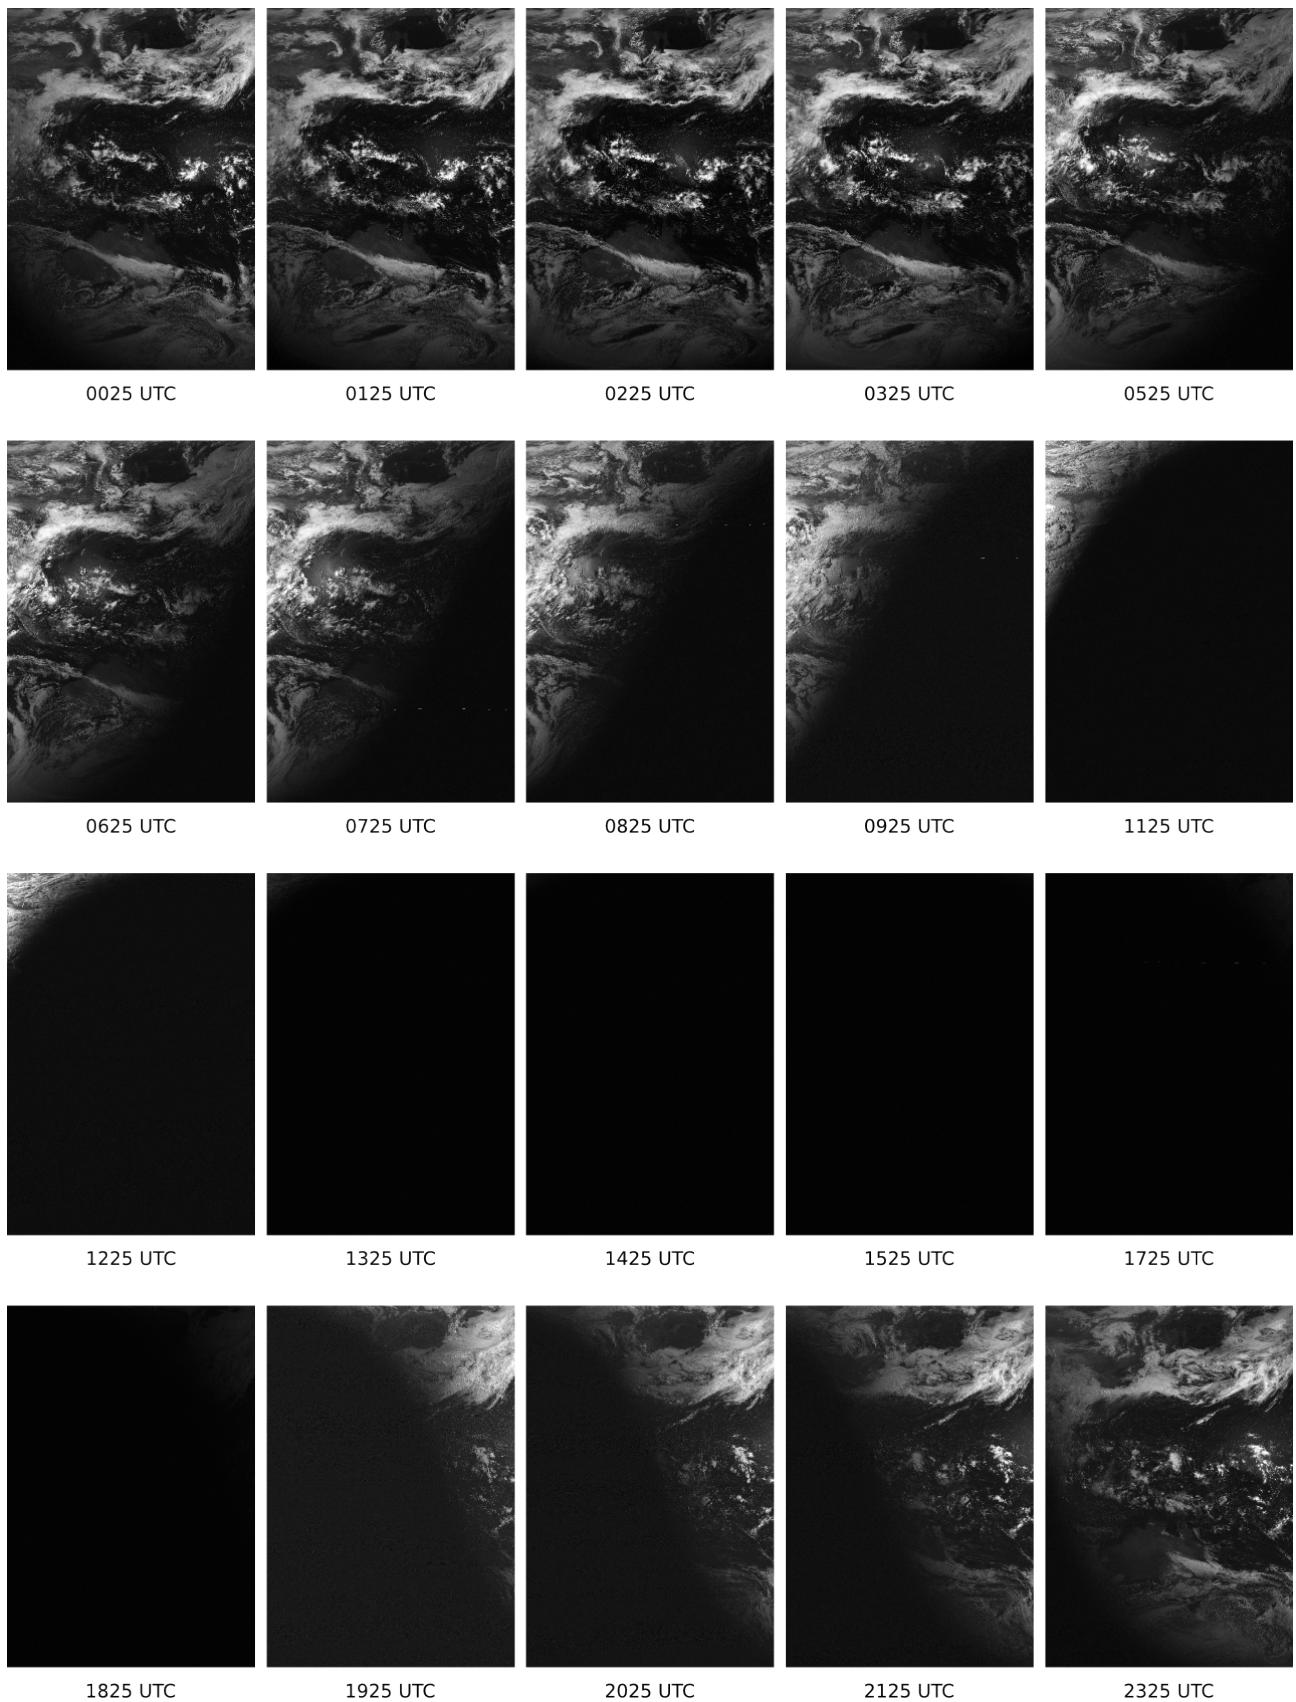

Figure 5.3: Regredded normalized scans performed by GOES-9++ (GMS) on a typical day (181).

The regredded imagery makes it possible to visualize the scans and test for possible

errors. The positioning of the imagery was tested and each picture was manually examined in the case of scan errors.

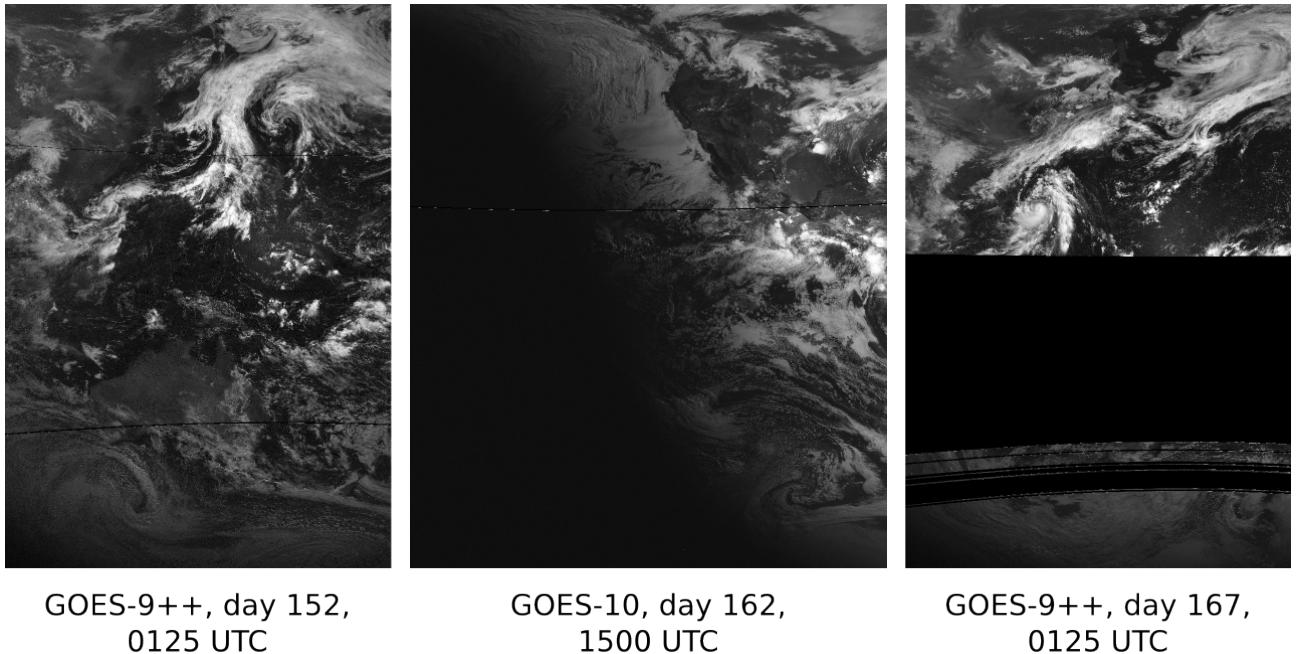

Figure 5.4: Examples of scan errors. The left two pictures are examples of minor errors, while the picture on the right shows a major error.

For the most part, the imagery was free of visible flaws. Minor errors that did occur were restricted to single, unscanned rows (see the left two panels of figure 5.4). Such errors were considered nonessential and ignored. In the case of major errors, such as when a large portion or even the entire scan was missing (see right panel of figure 5.4), the scan for that time slot was removed from the analysis to prevent subsequent errors. All other scans with only minor errors or no errors served as inputs in the following steps. Table 5.1 provides an overview of scan errors by satellite.

Table 5.1: Satellite scan errors that were found during visual evaluation of the scans used for the study. All scan errors that could be visually identified were noted. Most errors were minor, being restricted to a single line, and were ignored. Major scan errors led to a scan not being included in the following steps.

Satellite	Minor errors	Major errors	Errors / Total scans
GOES-9++ (GMS)	65	2	67 / 596 (11%)
GOES-10 (GOES-W)	1		1 / 232 (0%)
GOES-12 (GOES-E)	0	10	10 / 240 (4%)

In the regridded data, both land, sea and clouds can be distinguished clearly. It is also possible to observe how clouds move across the earth's surface and the sun's position

relative to the earth changes in the course of the day, as was expected.

5.2. Cloud albedo

The regridded imagery was used to produce rasters of the cloud albedo. Examples of typical days for each satellite that produced CAL data can be seen in figures 5.5, 5.6, 5.7 and 5.8. Because no CAL data was available from the precomputed Meteosat IODC scans, only typical days for GOES-W, GOES-E, Meteosat Prime and GMS are presented.

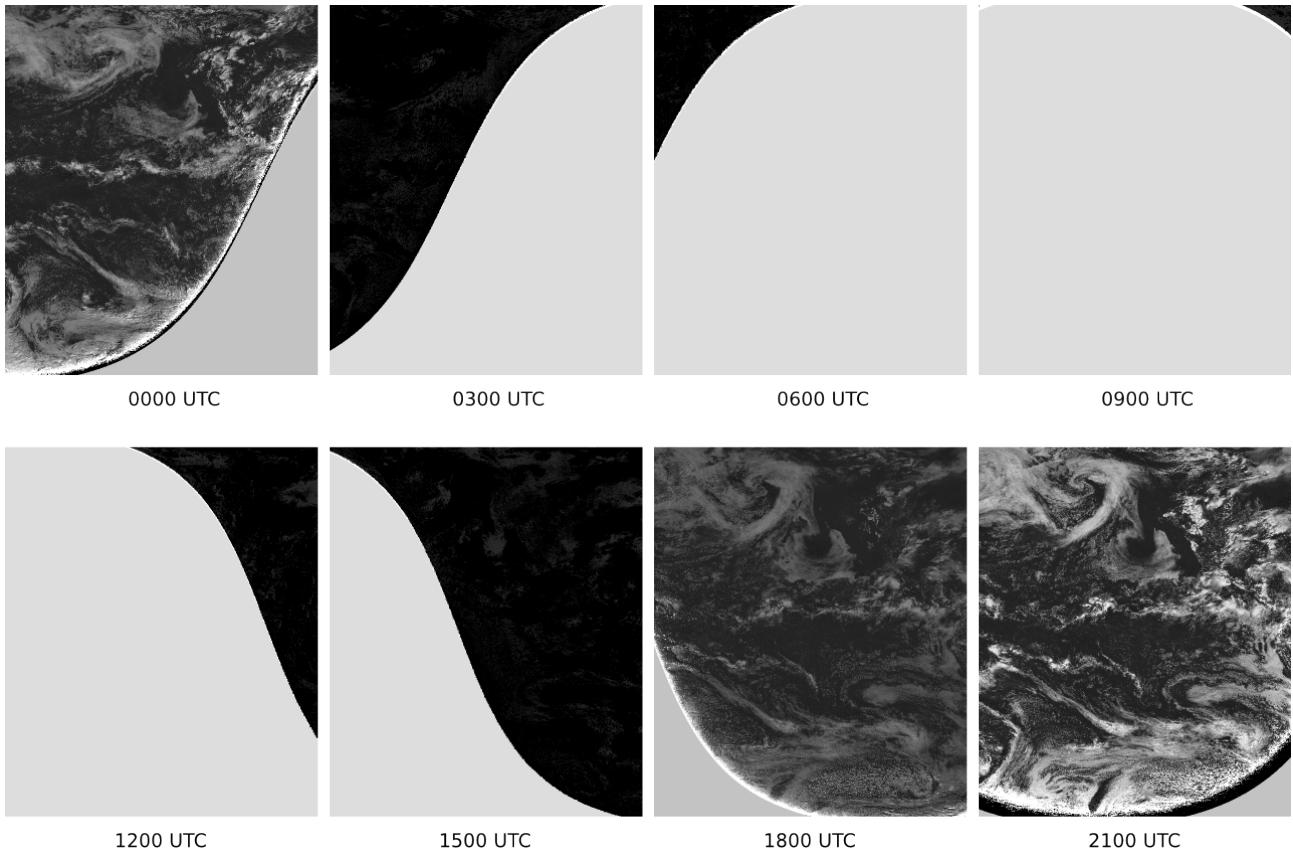

Figure 5.5: Normalized cloud albedo values, computed with GOES-10 (GOES-W) scans on a typical day (167). Brighter pixels denote higher effective cloud albedos.

As figure 5.5 shows, typical cloud formations can be distinguished on the imagery produced by GOES-W. The western North American coast, which is visible on the original scans, cannot be directly discerned when examining the CAL imagery. Instead, a large cloud-free area is shown in its place, which is consistent with the climatic conditions local to that region. Unfortunately, the quality of the produced data seems to deteriorate at the edges of the satellite's scan field, as can be seen on the 0000, 1800 and 2100 UTC time slots. Performance also seems to decrease rapidly at low solar zeniths, as can be seen on slots 0300, 1200 and 1500 UTC.

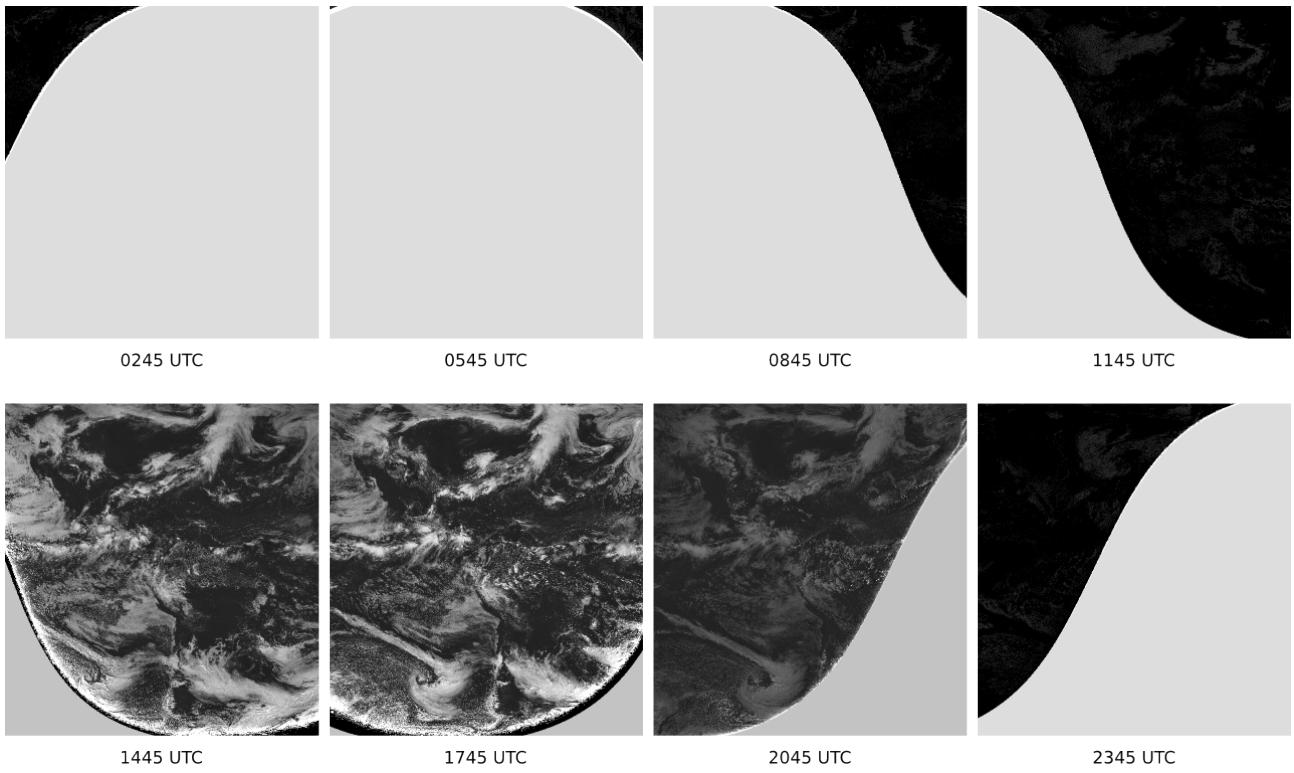

Figure 5.6: Normalized cloud albedo values, computed with GOES-12 (GOES-E) scans on a typical day (171). Brighter pixels denote higher effective cloud albedos.

There is much more land in GOES-E's viewing field, as shown in figure 5.6. Although the North and South American continents cannot be seen directly, their effects on cloud formation are readily visible, most notably at the 1445 and 1745 UTC time slots. The continental outlines are readily visible at the western South American coast, where the Andes produce large amounts of clouds. To the south, a large cloud-free region is visible, as well as over North America's western coast. Easterly clouds traveling with the trade winds can also be seen quite clearly.

Unfortunately, GOES-E seems to suffer from the same difficulties as GOES-W when viewing the planet at low solar zeniths. Time slots 0845, 1145 and 2345 UTC provide almost no information, and the entire viewing field captured at 2045 UTC contains unrealistically low cloud albedo values. Anomalously high values at the edges of the disc can be observed during the high solar zenith observation periods as well.

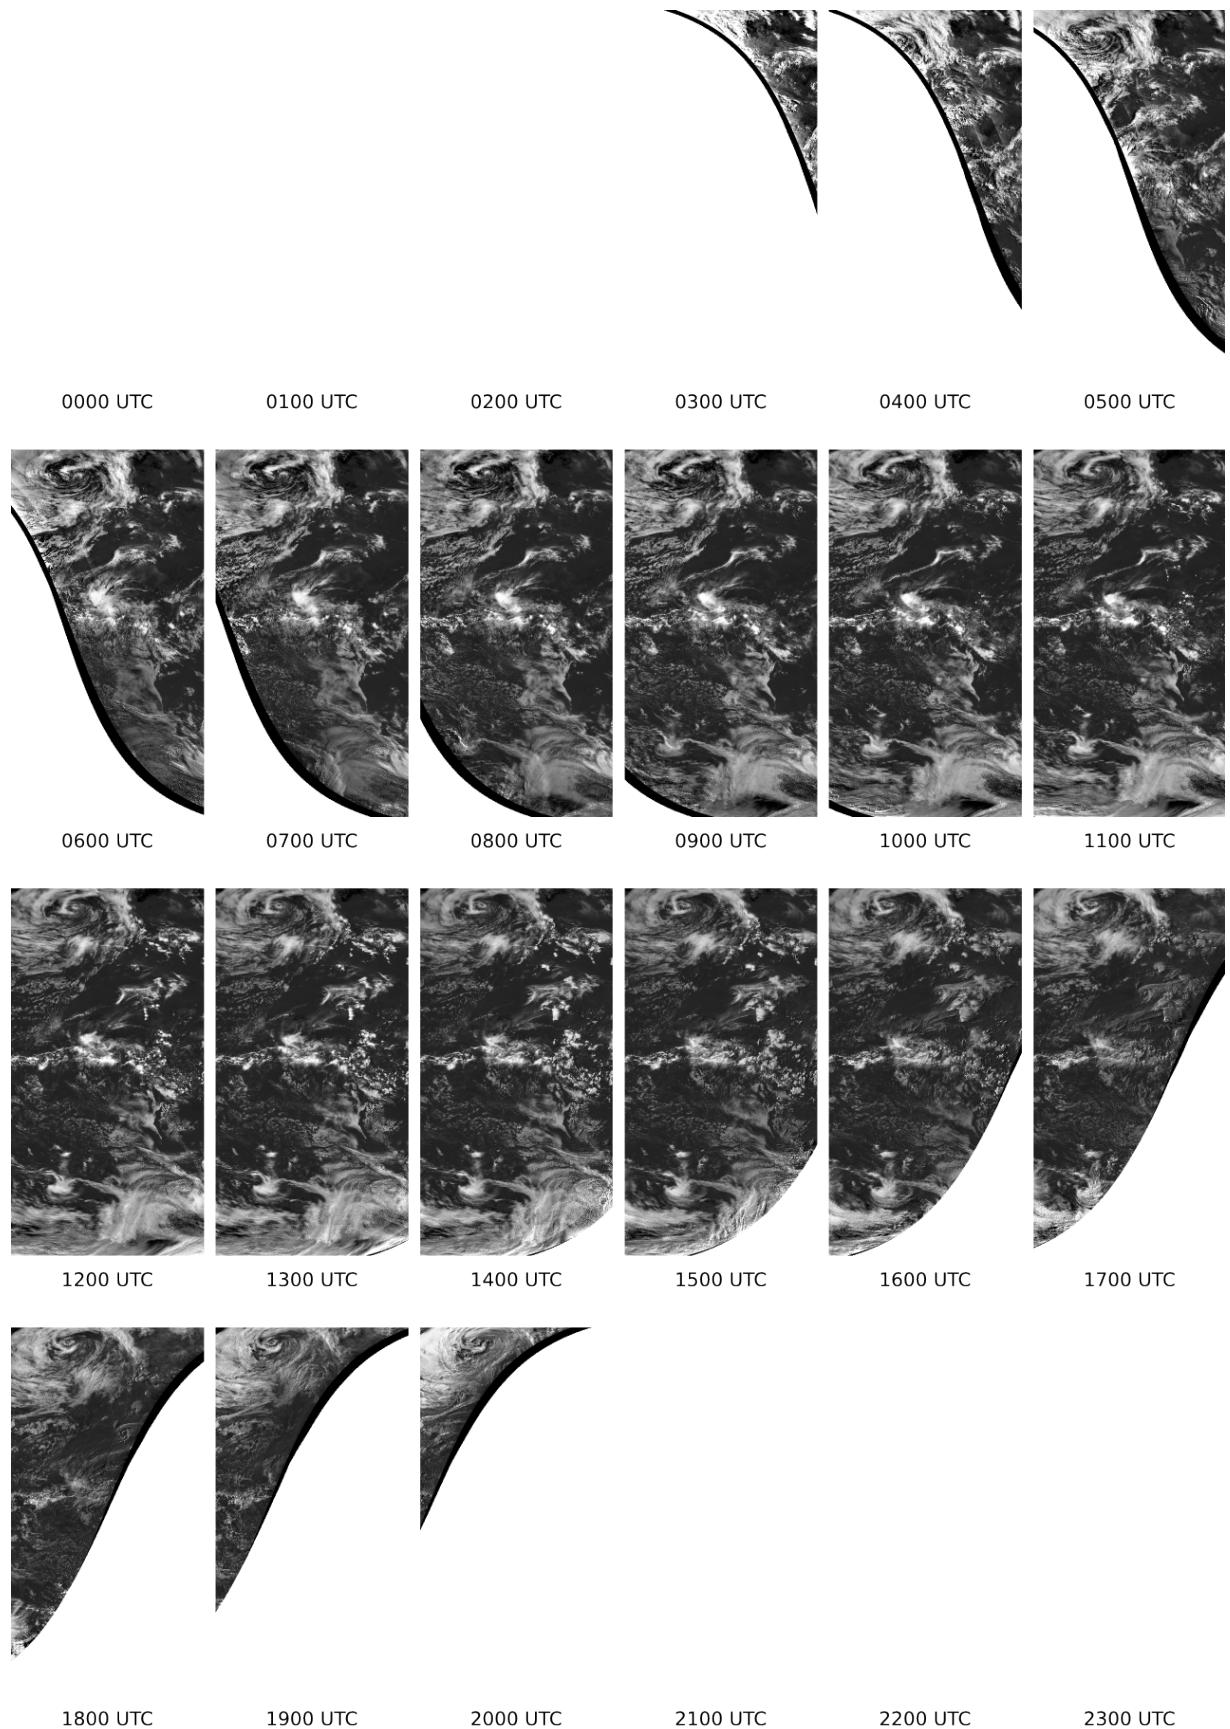

Figure 5.7: Normalized cloud albedo values, computed with Meteosat Prime scans on a typical day (153). Brighter pixels denote higher effective cloud albedos.

Figure 5.7 shows the cloud albedo imagery generated by Meteosat Prime. It is immediately apparent that Meteosat Prime performs better than both GOES-W and E, producing realistic imagery even during viewing periods with low solar zeniths. Both the twilight time slots at 0300 UTC and 2000 UTC show discernible, realistic cloud formations.

As is the case with the other satellites, the land is successfully removed from the picture by MAGICSOL's autocalibration technique. The effects of land on cloud cover, however, are nonetheless visible, especially over the Saharan desert in the northern portion of the imagery.

Aside from its higher quality imagery, Meteosat Prime has the advantage that it produces hourly full disc images. Thus the dispersal of clouds pushed by the trade winds off the west African coast can be readily observed, as well as compact cloud cover southwest of the African coast. The evolution of a cyclone in the northwest region of Meteosat Prime's viewing field can be followed without difficulty.

A possible error in the generated values can be seen on the western side of the cyclone during time slot 2000 UTC. Here the computed cloud albedo seems to be oversaturated, possibly due to sun glint.

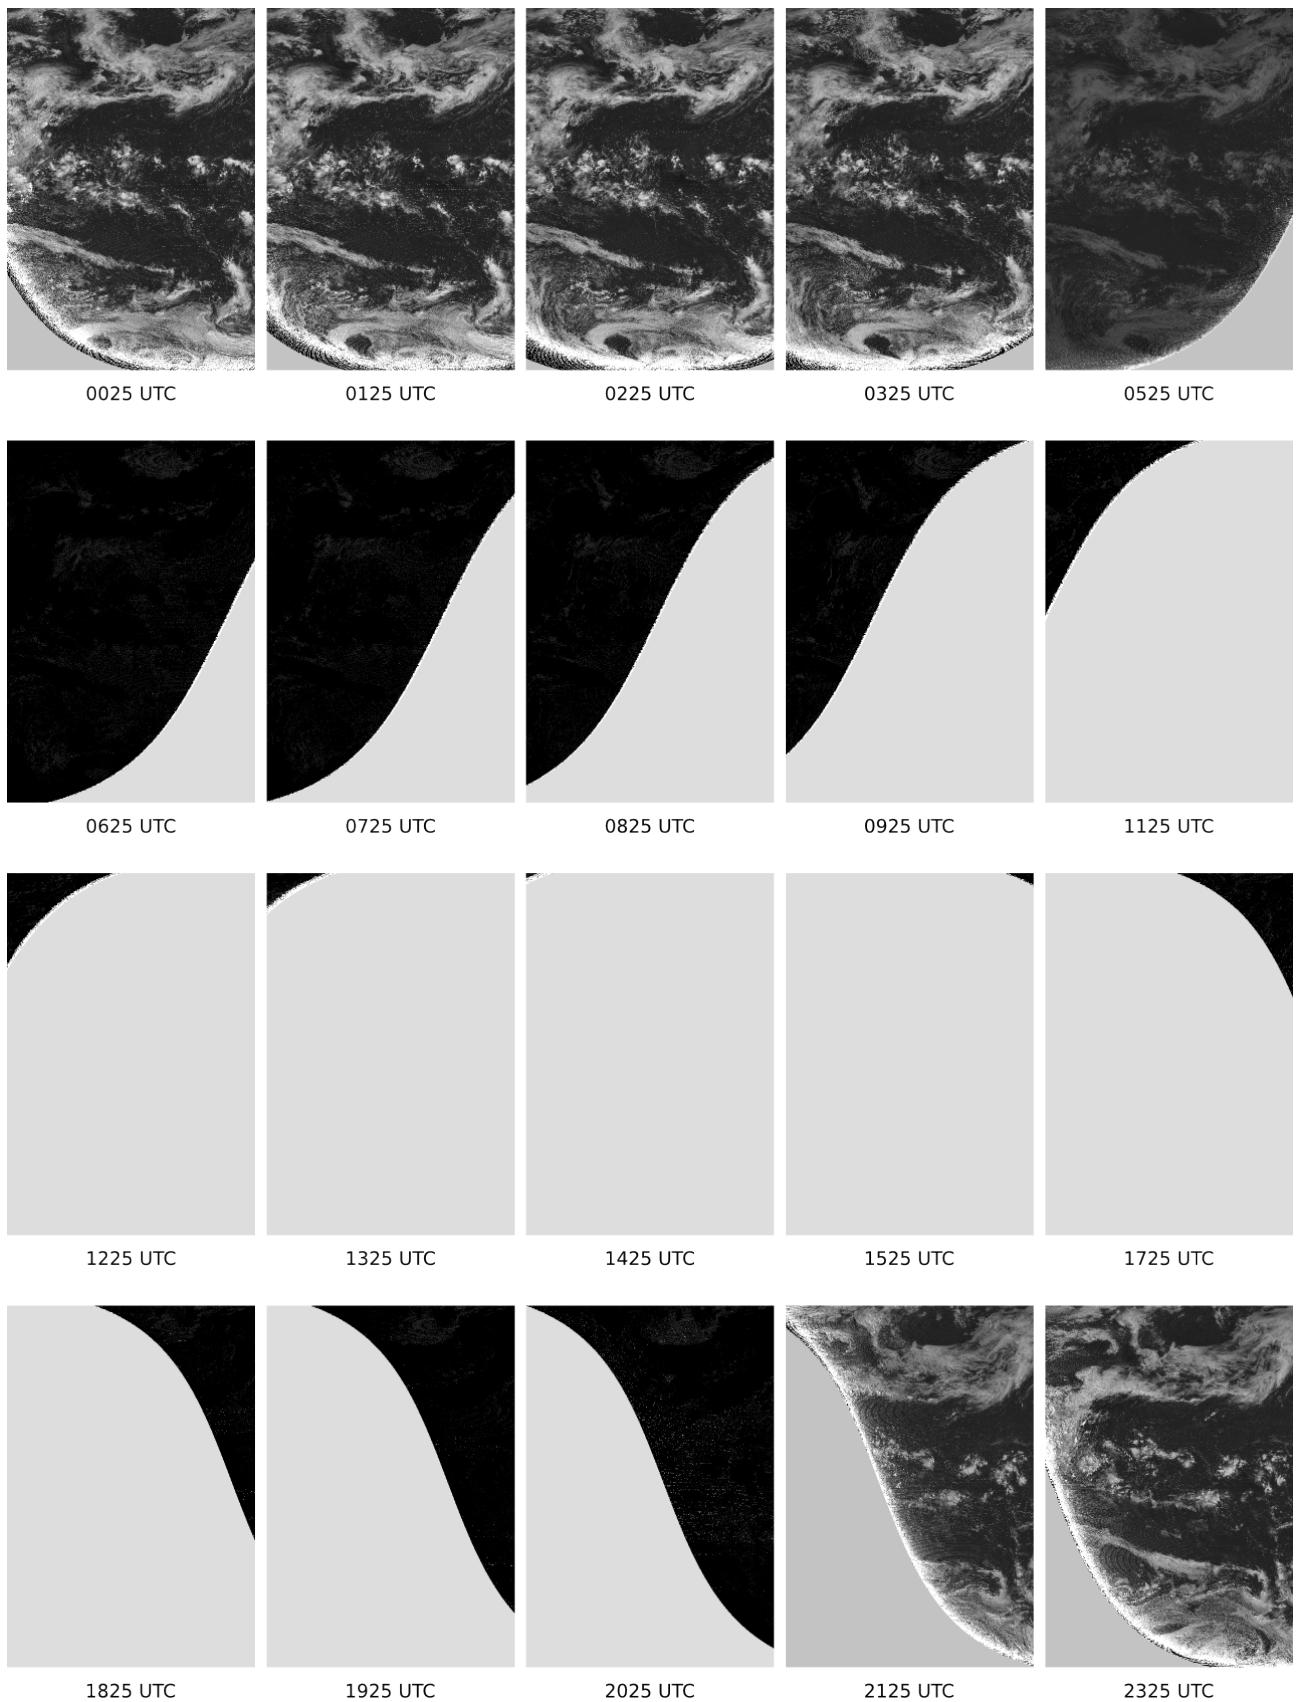

Figure 5.8: Normalized cloud albedo values, computed with GOES-09 (GMS) scans on a typical day (180). Brighter pixels denote higher effective cloud albedos.

The GOES satellite at the GMS position images at a higher temporal resolution than

GOES-W and E, but seems susceptible to the same weakness as the other satellites in the same series. As shown on figure 5.8, only the time slots between 2125 and 0325 UTC seem useful, with the slot at 0525 UTC showing unrealistically low CAL values. The following images seem entirely unsaturated, despite the fact that 0625 and 0725 UTC were taken during relatively high solar zeniths. For reasons unknown to the author, good imagery was produced during the 2125 UTC time slot, despite the fact that the solar zenith was lower than during 0625 UTC, where almost no clouds were detected. A possible reason for this could be improperly modeled solar geometry – if the solar position is computed incorrectly, it would explain these anomalies.

The data produced during useful scans, however, appears to be realistic. The easterly flow of clouds with the trade winds can be observed on the daytime scans, as well as the clearly demarcated, cloud-free subtropics.

In addition to inspecting the cloud albedo values by themselves, they were compared with MODIS cloud fraction maps. For a selection of overlapping simultaneous imagery collected with the GOES Imagers and the MODIS sensor, see figure 5.9.

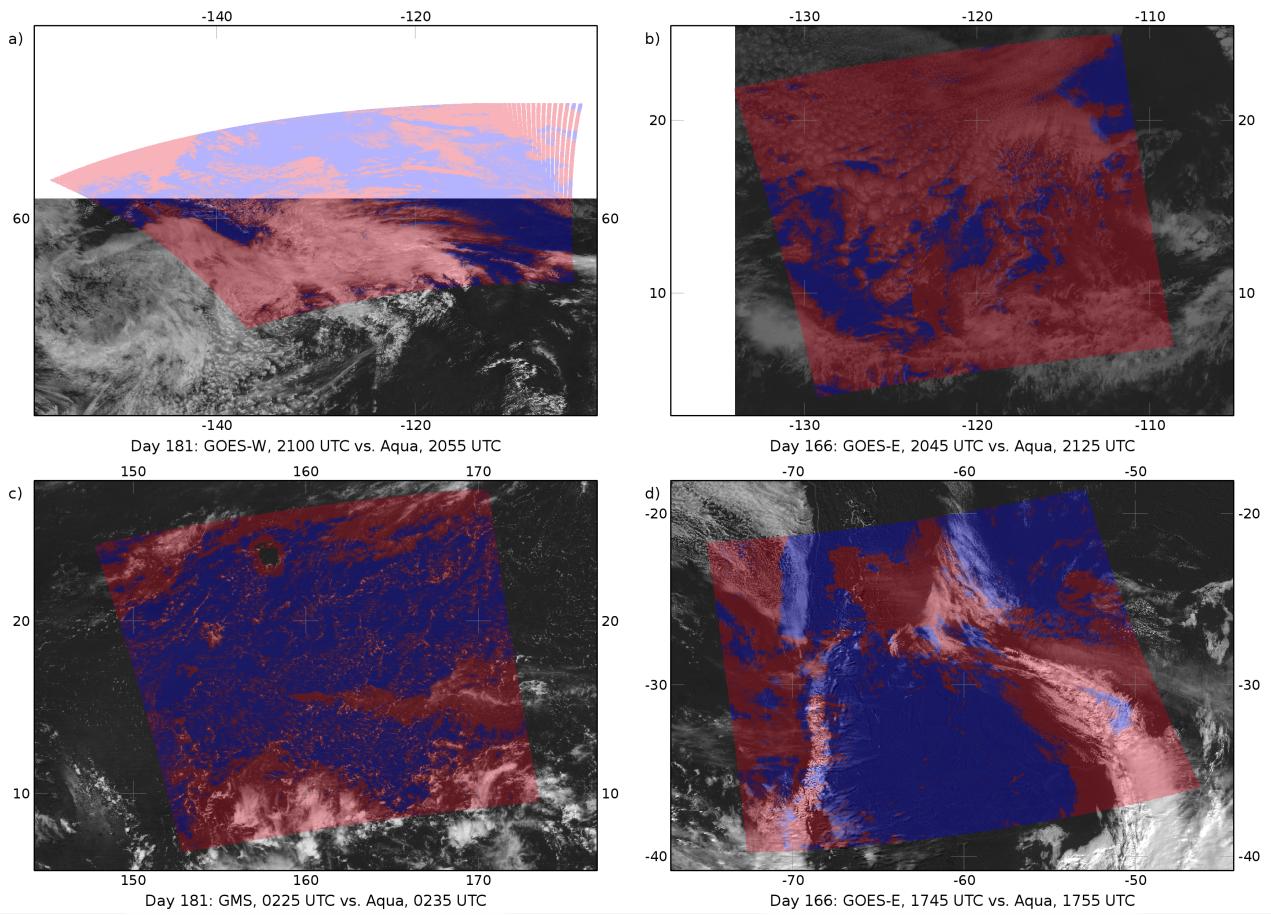

Figure 5.9: Examples of generated CAL values compared to MODIS cloud fraction maps. The generated CAL values are in gray tones, with brighter pixels denoting higher effective cloud albedo. The MODIS cloud fraction is classified on a blue-to-red scale, with blue denoting low cloud cover and red high cloud cover. Based partly on (National Aeronautics and Space Administration 2012).

As can be seen in panels a, b, and c, the agreement behind both cloud images is quite promising. Panel d is an example of low agreement. However, the same cloud formations can be recognized in both pictures, albeit at different positions. The Aqua satellite viewed the scene at 1755 UTC, whereas GOES-E viewed the same position during a scan starting from the northernmost part of the full disc at 1745 UTC. Because of the scene's location in the southern hemisphere, it was probably viewed several minutes after the Aqua observation. This suggests that the clouds were correctly detected by both satellites, and that they had moved between scans.

5.3. SID

The SID imagery was produced using the computed cloud albedo values and the climatologies as inputs for the LUTs contained in the MAGICSOL software. Examples of typical days can be seen in figures 5.10, 5.11, 5.12, 5.13 and 5.14.

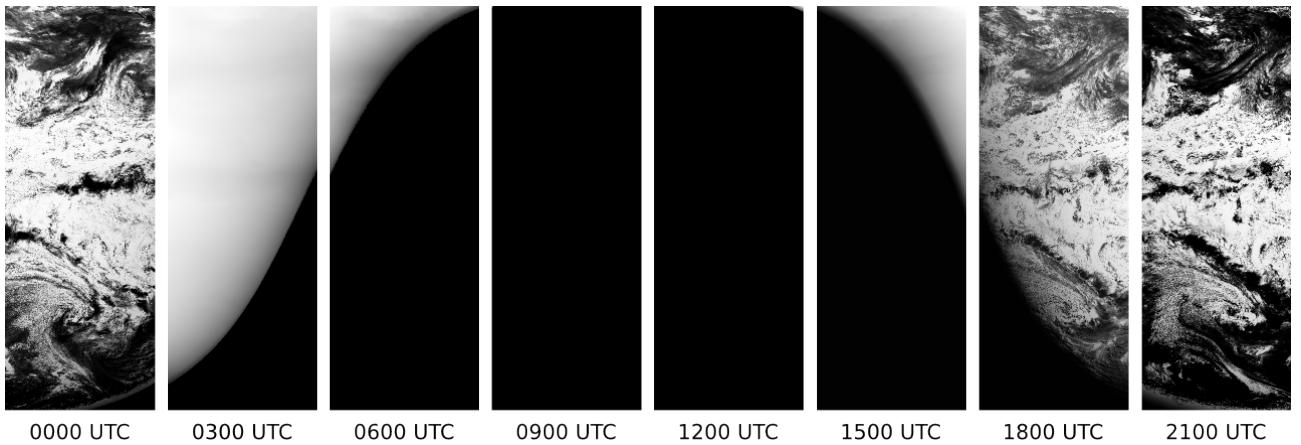

Figure 5.10: Normalized direct irradiation values, computed with GOES-10 (GOES-W) scans on a typical day (178). Brighter pixels denote higher SID values.

Figure 5.10 shows the SID data produced using GOES-W. A first glance reveals that the problems with low-zenith imagery that were noted in chapter 5.2 were carried over into the produced imagery. In contrast to these low-quality pictures, the high-zenith imagery appears to have a high degree of accuracy. The radiation distributions are as would be expected. Sharp cloud outlines are visible, especially in the north and south of the scan region, whereas the subtropics are noticeable cloud-poor.

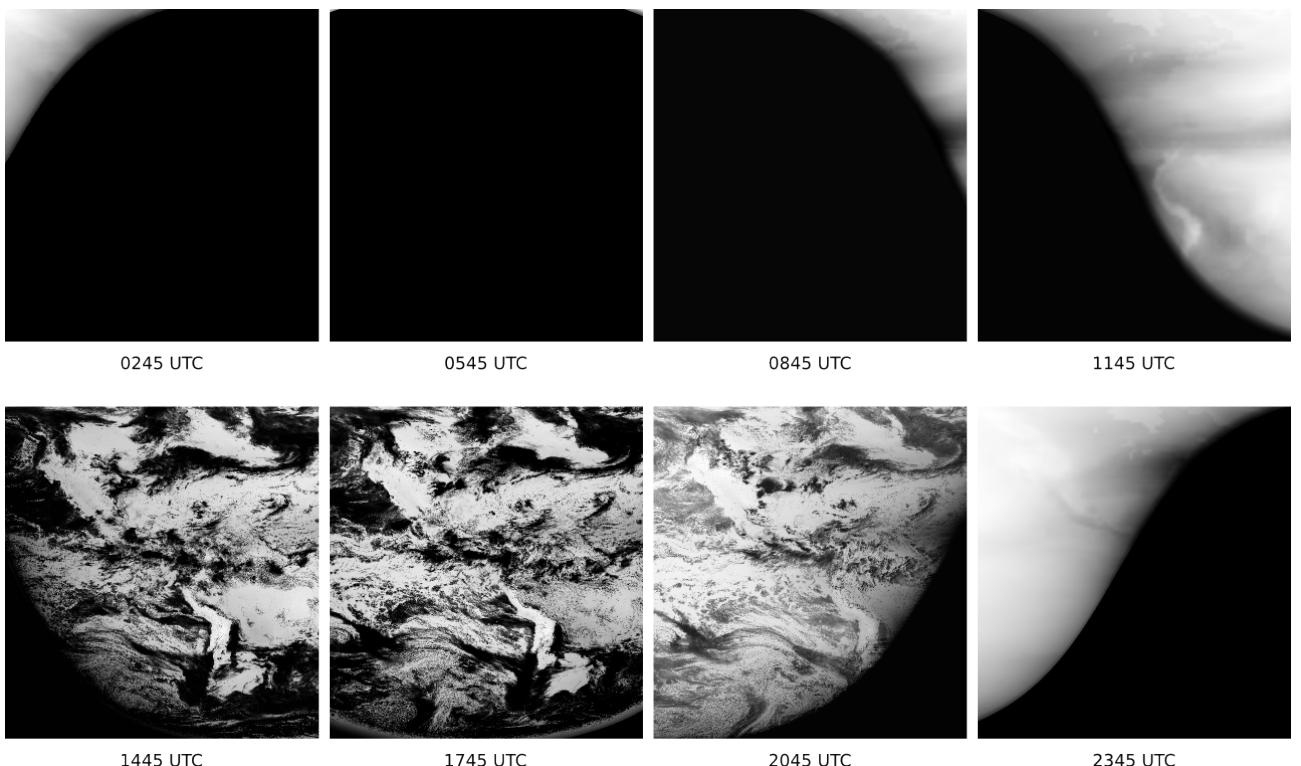

Figure 5.11: Normalized direct irradiation values, computed with GOES-12 (GOES-E) scans on a typical day (164). Brighter pixels denote higher SID values.

GOES-E appears to have performed similarly to GOES-W. The washed-out scans appear

to have failed to account for clouds and have artificially high irradiation values, as can be seen on figure 5.11 at 2045 UTC, but even more apparently from 2345 to 1145 UTC. Of the eight scans produced in a given day, two appear to have produced very good data and one data with limited usefulness. The rest of the images look very unrealistic.

The time slots at 1445 and 1745 UTC, however, did produce realistic data. Areas with high irradiation, such as the Sonoran and Atacama Deserts, are readily apparent, as are the clouds developing in the lee of Argentina off South America's western coast.

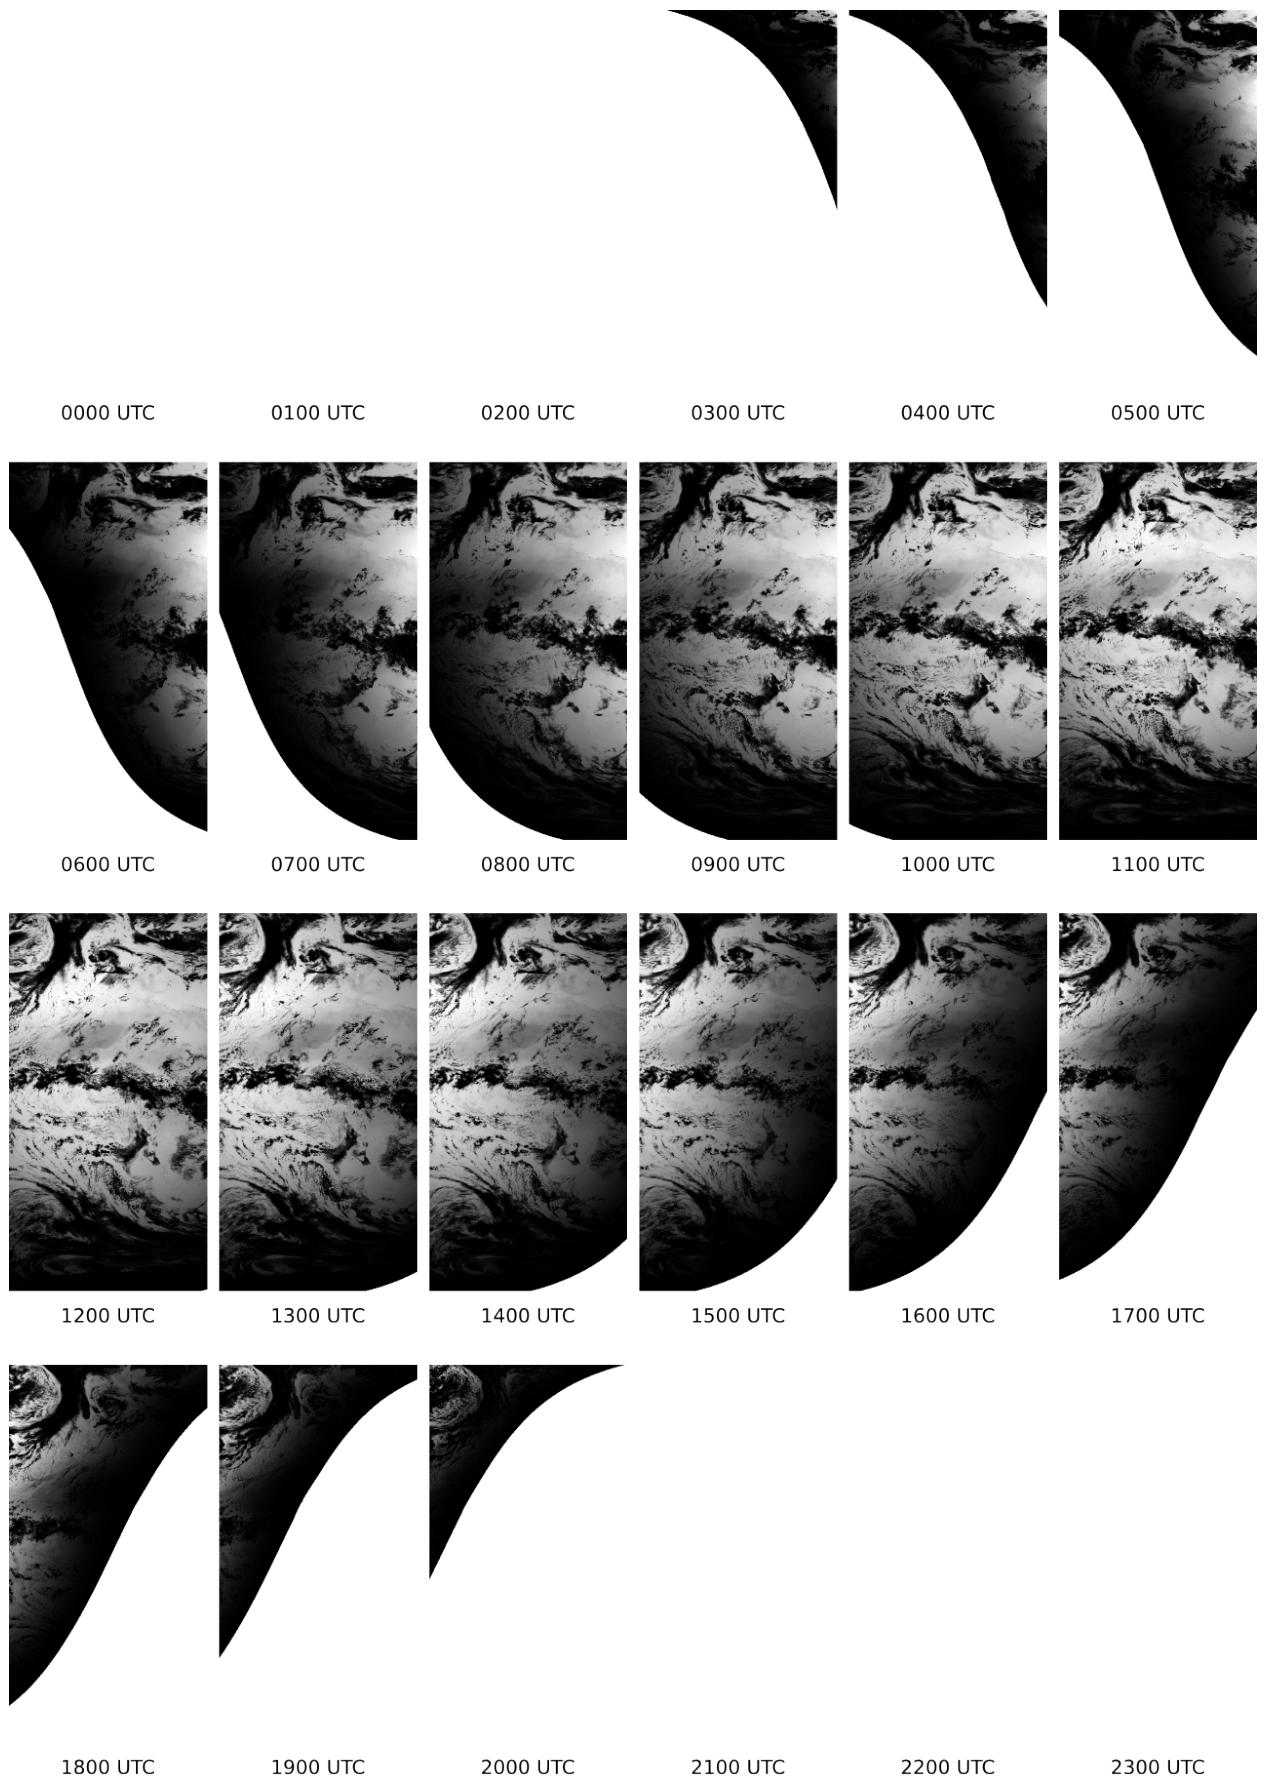

Figure 5.12: Normalized direct irradiation values, computed with Meteosat Prime scans on a typical day (176). Brighter pixels denote higher SID values.

As was the case with CAL, Meteosat Prime produced very promising SID data. As figure 5.12 demonstrates, the problems visible on the GOES imagery in twilight regions seem not to have affected the Meteosat imagery. The areas near the day-night border for which very low irradiation values were computed seem to correspond with dusk lighting conditions. Cloud-poor regions corresponding with the Sahara and Kalahari are easy to recognize, as well as clouds driven by the trade winds between South America and Africa.

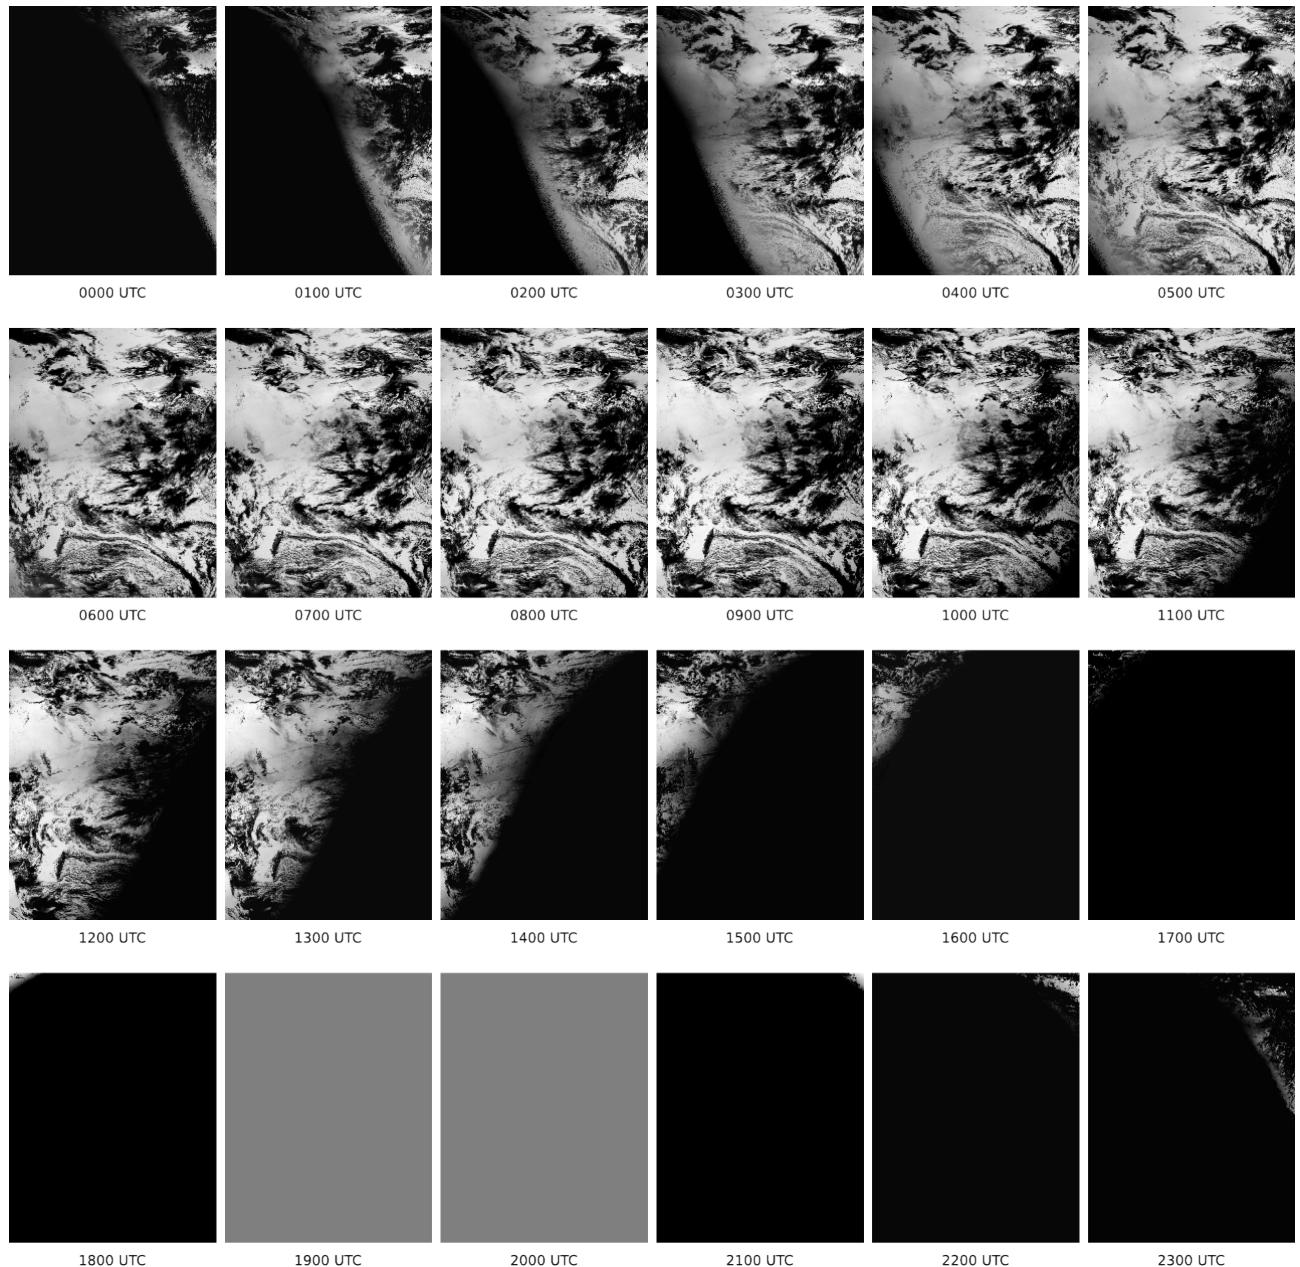

Figure 5.13: Normalized direct irradiation values, computed with Meteosat IODC scans on a typical day (181). Brighter pixels denote higher SID values.

The imagery collected by Meteosat IODC, shown on figure 5.13, also contains very promising values. As was the case with Meteosat Prime, twilight zones were captured

nicely, with realistic cloud formations visible up to the day-night border.

The daytime pictures contain many details that suggest that the data produced is realistic. Clouds, apparently caused by easterly winds in the southern region of the satellite's viewing region, can be recognized, as well as high irradiation over the Middle East.

Interestingly, in the day shown there is an artifact in the upper portions of the images. Also, the nighttime time steps 1900 and 2000 UTC seem to show positive irradiation values. This is an artifact of the picture normalization in order to make details more easy to recognize and is not contained in the original data.

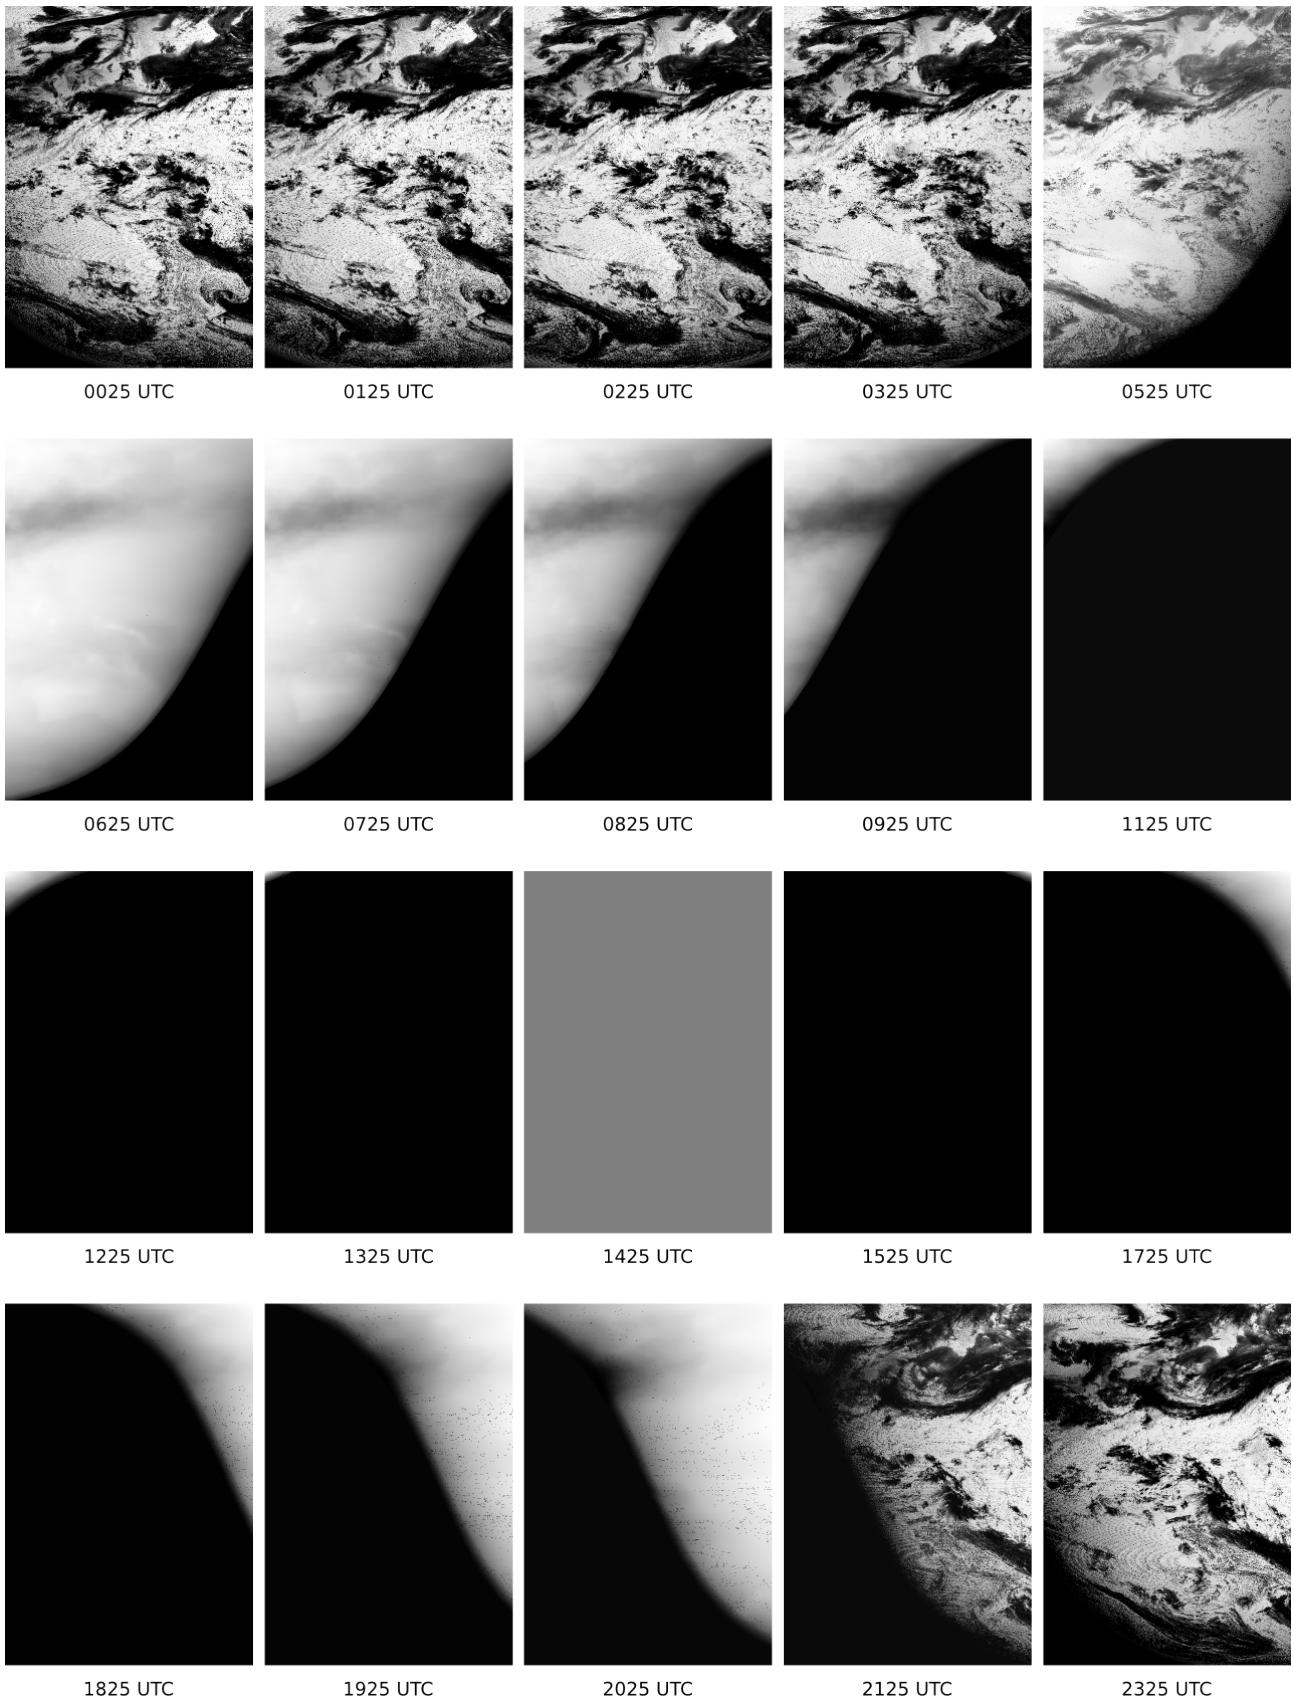

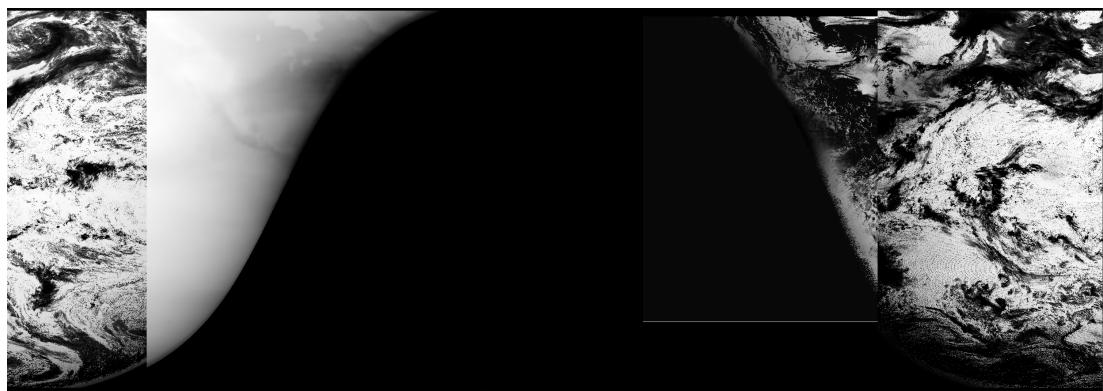

Figure 5.14: Normalized direct irradiation values, computed with GOES-09++ (GMS) scans on a typical day (160). Brighter pixels denote higher SID values.

GOES-09++ at the GMS position produced promising data during the daytime time slots,

as shown in figure 5.14. Unfortunately, as was the case with all three GOES satellites, twilight time slots resulted in washed-out data. Cloud cover to the east of Japan can be discerned, as well as south of Australia. Australia is easily recognizable due to its high irradiation values in comparison with the surrounding ocean. On all daytime pictures, regridding artifacts can be seen in the form of oval-shaped rings. This is, however, a result of the regridding procedure and not caused by the MAGICSOL method.

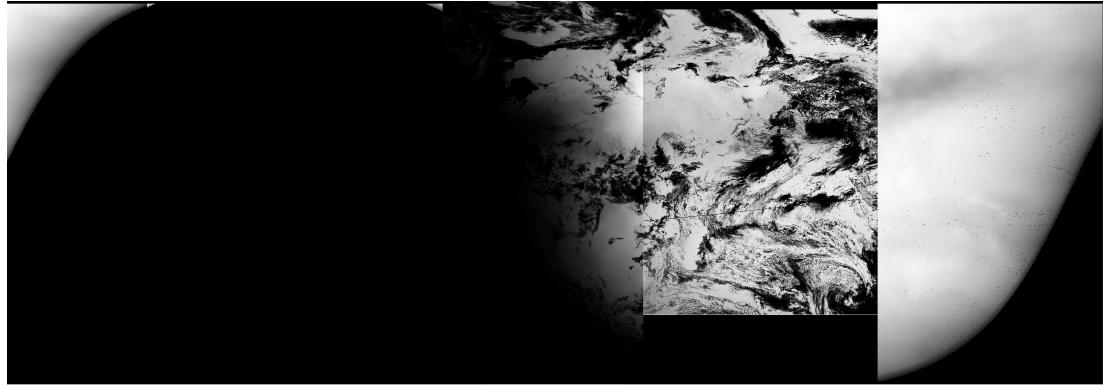

As explained in chapter 4.3, cross-satellite consistency was tested in part by creating merged global imagery from each satellite at near-simultaneous scan times. The results of this procedure can be seen in figures 5.15 and 5.16.

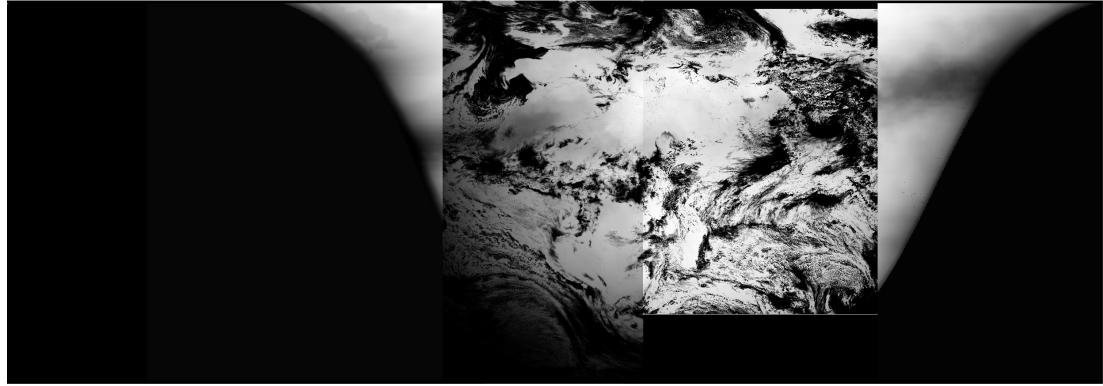

UTC 0000

UTC 0300

UTC 1800

UTC 2100

Figure 5.16: Hours 1200 – 2100 UTC on a typical day (171) of combined normalized SID imagery using all geosynchronous satellites.

The trends observed in the scans of each individual satellite can be seen in the global imagery. The areas where high amounts of irradiation should be expected exhibit high SID values, whereas cloudy areas have low SID values. Notably, cloud formations on the border of one scan area can be seen to continue on the adjacent satellite's scan, suggesting a high level of agreement between the satellites.

Unfortunately, the washed-out data produced by the GOES satellites prevents the creation of high-quality simultaneous global imagery throughout the entire day. The effects of this error can also be seen in the data's monthly means, as seen in figure 5.17.

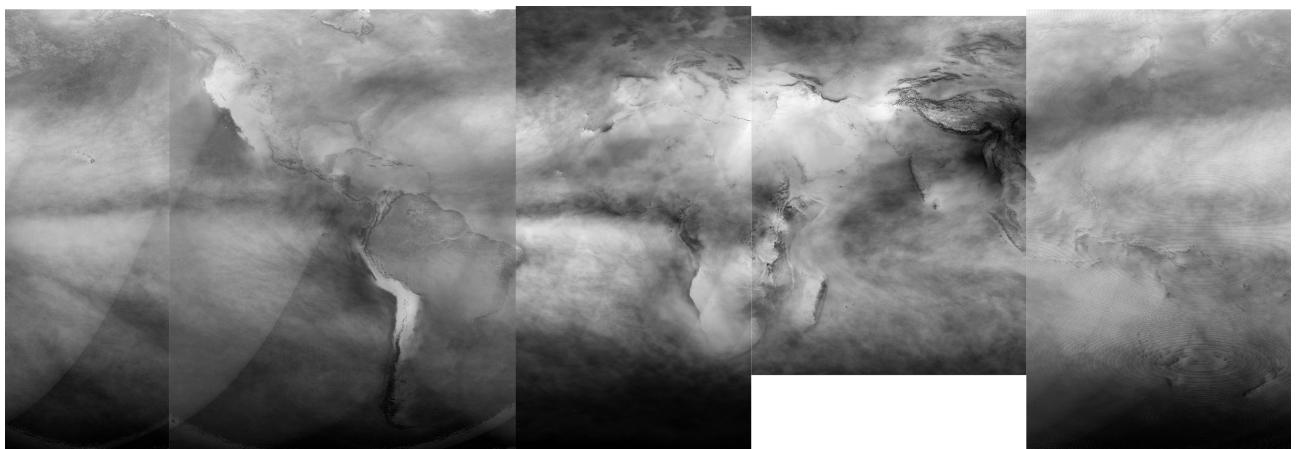

Figure 5.17: Normalized monthly averages of SID values produced from each satellite using the MAGICSOL method.

The monthly means of SID show the global trends that would be expected. However, the GOES imagery has much less contrast than the Meteosat imagery. This is most likely the result of the washing-out effect that occurs only in GOES imagery during low-zenith scans.

Nonetheless, the data looks fairly promising. The clouds resulting from the trade winds can be easily recognized, as well as clouds carried with the Asian summer monsoon, first northwest south of the equator and then northeast north of the equator as a result of the Coriolis effect. Areas with high cloud cover, such as in southeast Asia in the Meteosat IODC imagery, off the western coasts of North and South America in the GOES-E imagery and over the British Isles in the data produced with Meteosat Prime, can be readily recognized. Low cloud cover can be seen on the subtropics in the GOES-W imagery, on the North and South American west coasts in the GOES-E imagery, over the Sahara and Kalahari in the Meteosat Prime images, in the cloud shadow produced by Madagascar and over the Middle East, as captured by Meteosat IODC, and over Australia and the remaining subtropics in the GMS scans.

Interestingly, the day-night border is quite visible in the monthly means for each satellite, except for in the Meteosat IODC imagery. At this time it is unclear why the day-night border is so easily visible in the two adjacent satellites, Meteosat Prime and GMS, which both scanned with the same temporal resolution. One possible reason could be the fact that the Meteosat Prime imagery was cut off at the day-night border after its production, with null values on the night side of each scan. This was not a part of the MAGICSOL method and was not performed for Meteosat IODC, so that the Meteosat IODC imagery has a smoother, perhaps more natural transition from day to night. It was also not done for the GOES-9++ at the GMS position, but due to the washing-out effect observed in all GOES imagery, the day-night border in the GMS imagery is nonetheless quite sharply defined.

Another way of testing cross-satellite consistency was by evaluating the differences in computed SID for the same pixels. If the MAGICSOL method were to work perfectly, two satellites seeing the same position on the planet's surface simultaneously would produce exactly the same result. Of course, the MAGICSOL method is not entirely perfect, and even if this were the case, no pixel was observed at precisely the same time by two satellites. This is due to the fact that each satellite began its scan at different points in time and from different spatial origins. This is especially the case for the GOES satellites, which, in contrast to the Meteosat satellites, began their scans at different times, leading to discrepancies of up to 25 minutes between similar scan periods. Even when scans began simultaneously, as was the case for both Meteosat satellites, shared pixels would be scanned at slightly different times because they were located at different positions in each satellite's scan routine. This temporal discrepancy allows for changes in the scanned pixel's atmospheric state which would change the value that both viewing satellites produce. Clouds can develop or disperse quickly, and they also change their location depending on prevailing winds. Therefore, a deviation between two satellites' measurements of 0, especially over a larger region, would be highly unlikely. Nonetheless, low deviation, and thus high agreement, can be seen as a sign of consistent readings across the different satellites used. The results are shown in figures 5.18, 5.19, 5.20 and 5.21.

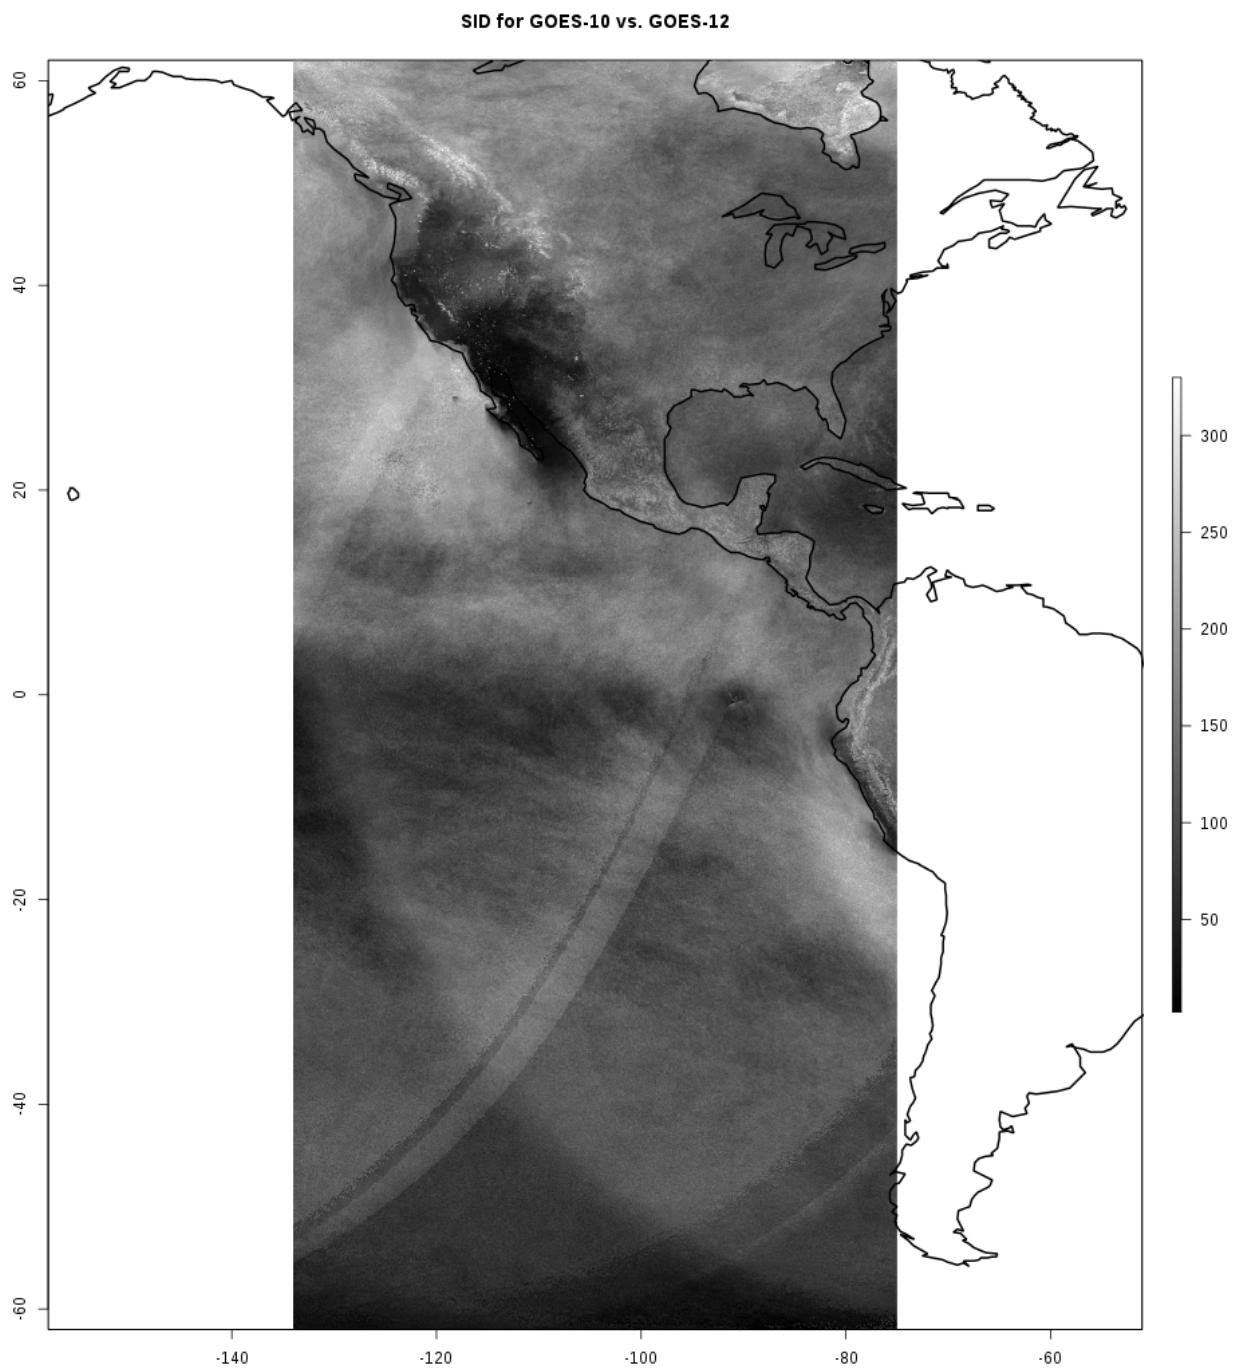

Figure 5.18: Deviance in monthly means of SID computed by GOES-W and GOES-E, measured in W / m^2 .

Figure 5.18 shows the deviance in SID monthly means, as computed by GOES-W and E. Areas with consistently low or high cloud cover show a high level of agreement. This can be observed in cloud-poor regions, such as over the Sonoran Desert and the San Joaquin Valley, as well as in cloud-rich regions, such as west of the Andes and off the South American coast, where trade winds blow clouds west. Low agreement is found over the

Rocky Mountains, possibly due to each satellite's independent snow tests, as well as over the Hudson Bay. Artifacts along the day-night border are also visible. This is clearly due to the data quality and not the result of meteorological phenomena.

Table 5.2: Differences in simultaneous observations obtained by GOES-W and GOES-E. Units are W / m².

Minimum	Maximum	Standard deviance	Mean
0.00	982.79	130.15	123.08

As shown in table 5.2, deviance between both satellites' SID values is quite low. The mean deviance is lower than that observed at most BSRN stations using a single sensor to produce minutely observations over the course of an hour. The BSRN stations' pyrheliometers occupy a much smaller area than a pixel observed by one of the satellites in question, and are thus more susceptible to rapid fluctuations in irradiation levels due to cloud cover. Nonetheless, this level of agreement between both satellites can be considered a sign that values produced with one are consistent with those produced by the other.

SID for GOES-12 vs. Meteosat Prime

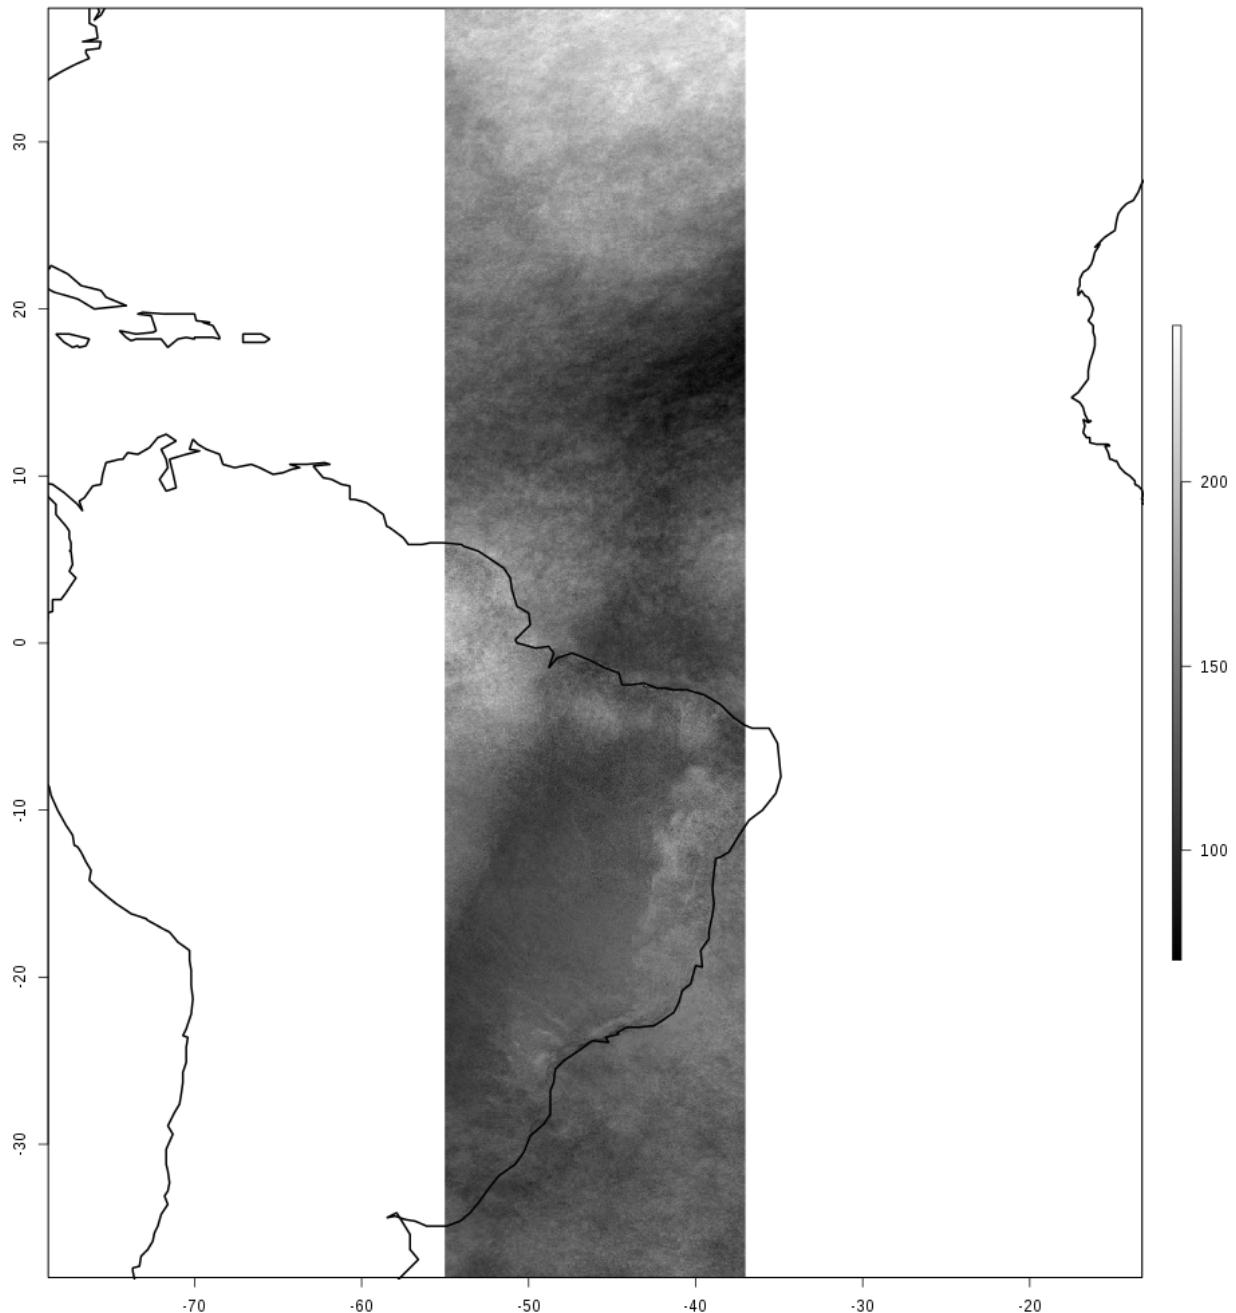

Figure 5.19: Deviance in monthly means of SID computed by GOES-E and Meteosat Prime, measured in W / m^2 .

The deviance between SID values produced by GOES-E and Meteosat Prime was similar to that in the previous example, as is shown in figure 5.19. The highest variability is in the northernmost portion of the overlap stripe, possibly due to the more variable cloud cover expected there during north summer. The lowest variability was observed north of South America, most likely due to consistent trade wind clouds.

Table 5.3: Differences in simultaneous observations obtained by GOES-E and Meteosat Prime. Units are W / m².

Minimum	Maximum	Standard deviance	Mean
0.00	924.79	109.62	141.74

A numerical summary of the deviance between GOES-E and Meteosat Prime can be found in table 5.3. The agreement in this area is quite satisfactory, as was the case with the overlap area of GOES-W and GOES-E. As the table shows, the deviance between GOES-E and Meteosat was quite low, but nonetheless higher than that between GOES-W and GOES-E. This could be the result of the twilight wash-out effect, which can be found in both GOES-W and GOES-E, but not in Meteosat Prime.

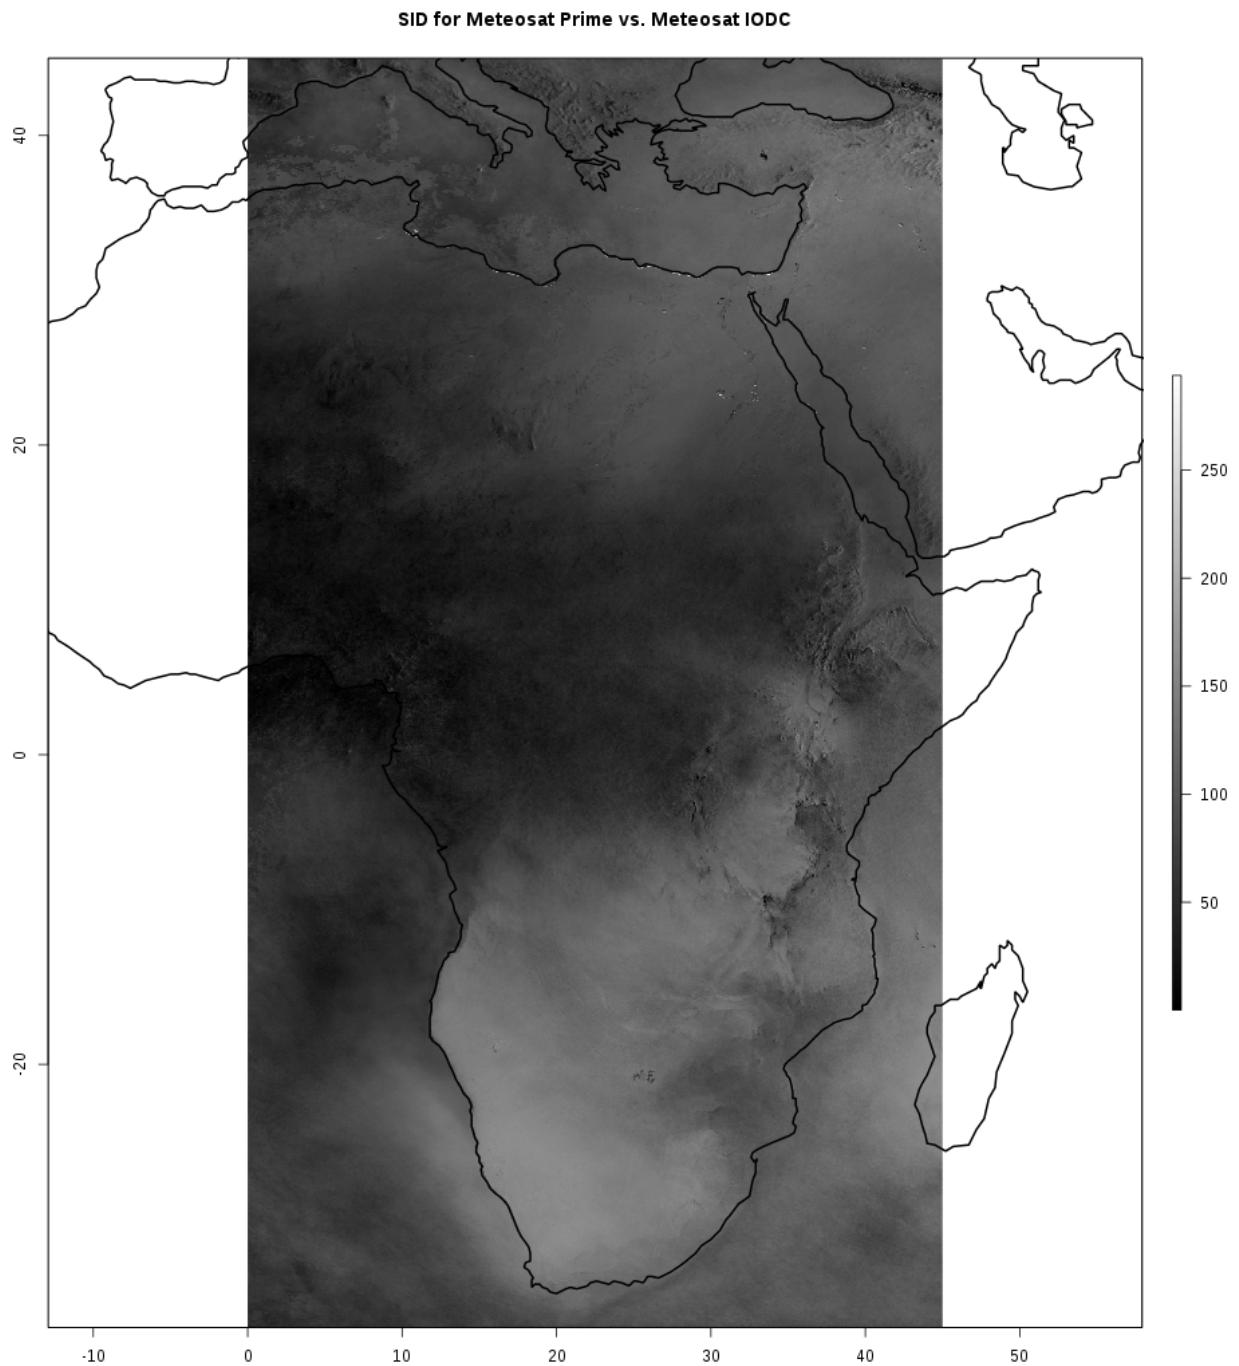

Figure 5.20: Deviance in monthly means of SID computed by Meteosat Prime and Meteosat IODC, measured in W/m².

The agreement between Meteosat Prime and Meteosat IODC, shown in figure 5.20, is even higher than that between the two previously compared satellite pairs. This is most likely due to the fact that both satellites begin their scans simultaneously, so that shared pixels are scanned at almost the same time.

The area with the least variability was over the Gulf of Guinea and the adjacent tropics.

This is likely due to consistently high cloud cover. Interestingly, Namibia and Saudi Arabia were among the areas with the highest variability, despite their general lack of cloud cover.

Table 5.4: Differences in simultaneous observations obtained by Meteosat Prime and Meteosat IODC. Units are W / m².

Minimum	Maximum	Standard deviance	Mean
0.01	293.84	35.21	82.28

Table 5.4 shows the numerical values corresponding to the map in figure 5.20. They confirm the high agreement between Meteosat Prime and Meteosat IODC.

SID for Meteosat IODC vs. GOES-09

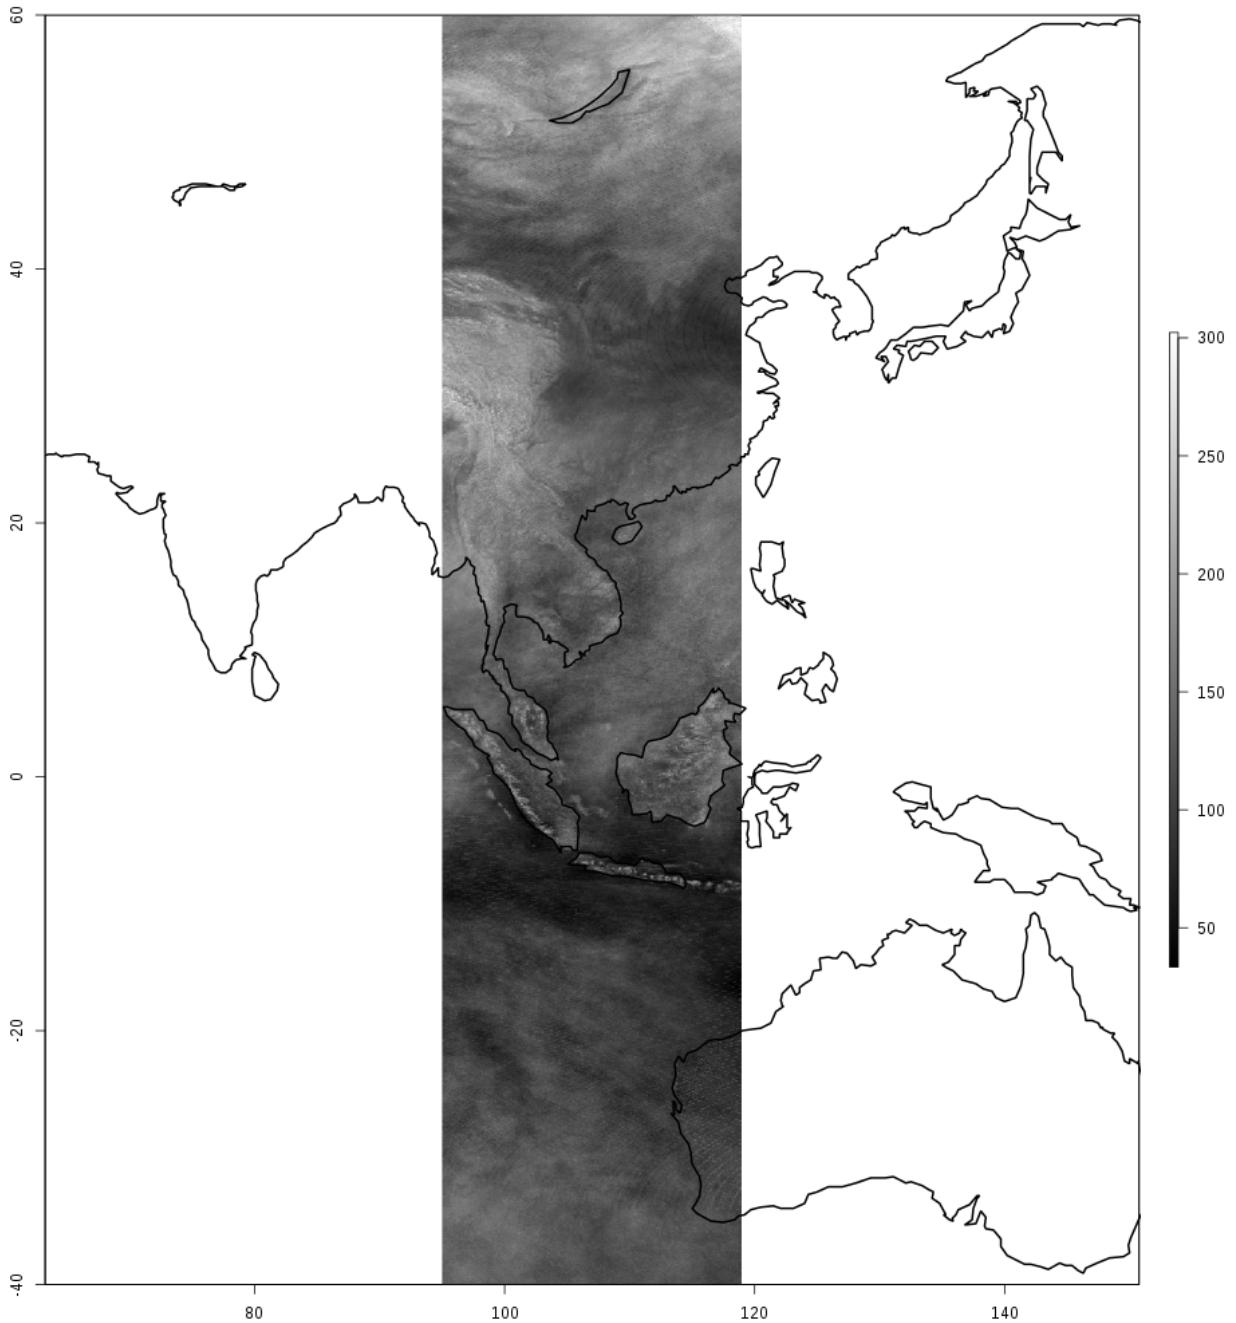

Figure 5.21: Deviance in monthly means of SID computed by Meteosat IODC and GMS, measured in W / m^2 .

Figure 5.21 shows the agreement between Meteosat IODC and GMS. The areas with the highest deviance are over continental Asia, whereas high agreement can be found over Indonesia in the tropics. Regridding artifacts can be seen around 37° north and south. The level of agreement is similar to that between GOES-W and E, as shown in table 5.5. This makes sense in light of the fact that Meteosat IODC begins its scan at the start of the hour, whereas GMS begins a half hour later.

Table 5.5: Differences in instantaneous observations obtained by Meteosat IODC and GMS. Units are W / m^2 .

Minimum	Maximum	Standard deviance	Mean
0.00	986.17	134.38	128.69

The agreement between the generated values and the validation data set, the BSRN ground measurements, are shown in figures 5.22 and 5.23.

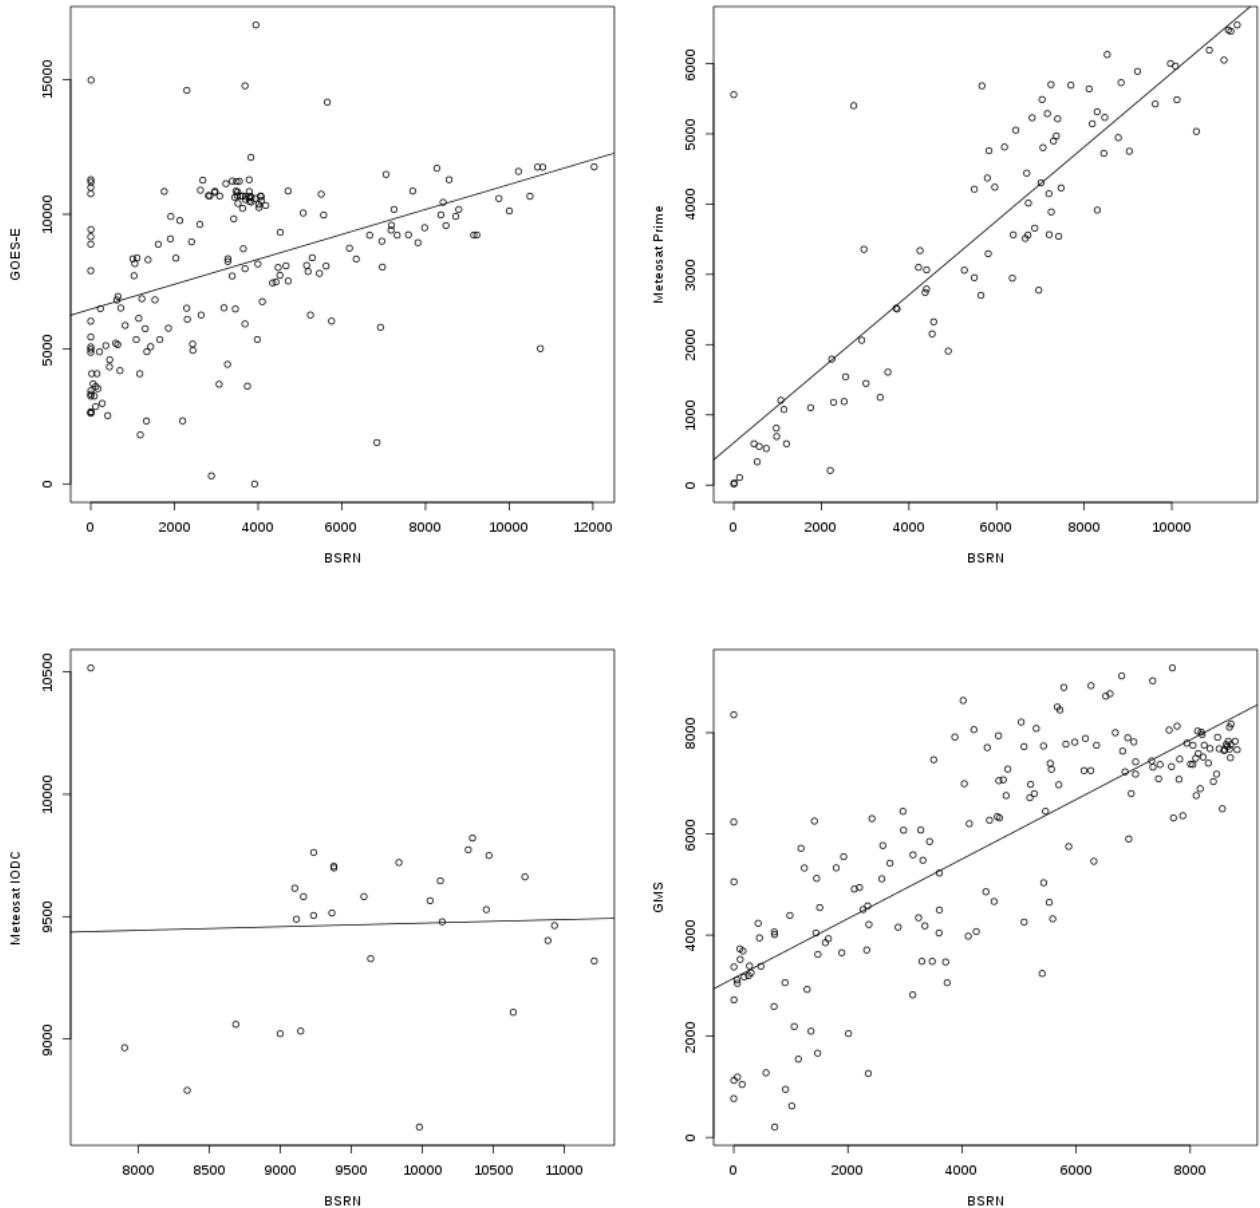

Figure 5.22: Computed SID values in daily sums of Wh / m^2 plotted against corresponding ground station measurements for each satellite. Clockwise from the top left: GOES-E, Meteosat Prime, Meteosat IODC, GMS.

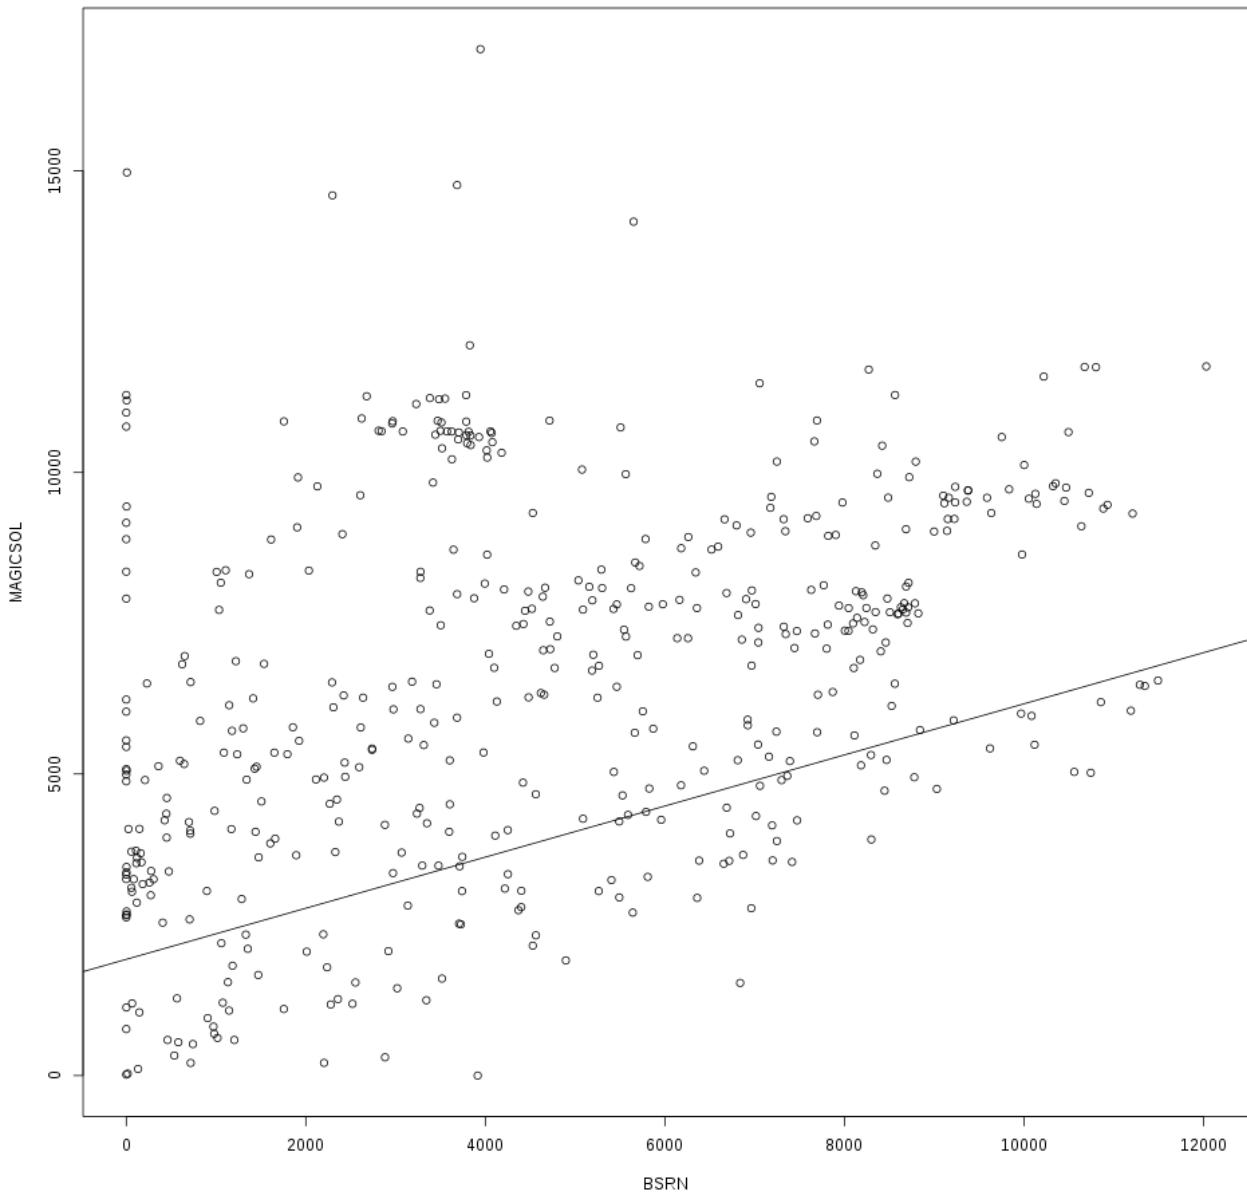

Figure 5.23: Computed SID values in daily sums of Wh / m² plotted against corresponding ground station measurements for all satellites.

As 5.22 shows, Meteosat Prime and GMS performed quite well. GOES-E also shows somewhat promising results, but they are not nearly as good as the other two satellites. This is surely due in part to the lower scan frequency of GOES-E. Meteosat IODC performed very poorly, although this low performance is mitigated by the fact that it is based on only one validation station. This limits the credibility of any statements about the quality of the data set. The same caveat is true for all satellites, although more stations were available to validate them. Because no validation stations were within the area of the SID data produced using GOES-W imagery, GOES-W could not be numerically validated.

Several measurements are notable, in which the BSRN station did not register any SID at all, while the data produced with MAGICSOL showed larger irradiation values. These values are mostly due to some kind of instrument failure at the station. Such instrument errors are not specific to a single station and artificially lower the validation scores (for more information, see chapter 5.5).

A combined comparison of all SID data produced with MAGICSOL and all corresponding station measurements is shown in figure 5.23. On a whole, the data is characterized by a wide dispersion, whereas a pattern of agreement is discernible.

Table 5.6: Validation of daily SID measured by each satellite, compared with BSRN ground measurements. Acronyms: MAD: mean absolute difference; SD: standard deviance; AC: anomaly correlation; RMSE: root mean squared error; Frac: Fraction of time steps above validation threshold. Units: W / m², for AC and Frac %.

Data source	Number of stations	Bias	MAD	SD	AC	RMSE	Frac
GOES-E	13	191.43	200.24	132.48	0.43	232.59	0.94
Meteosat Prime	9	-86.53	94.79	72.79	0.87	112.81	0.82
Meteosat IODC	1	-8.35	29.63	39.25	0.04	39.48	0.30
GMS	7	53.90	73.28	75.06	0.78	92.24	0.74
MAGICSOL (all)	30	75.25	122.20	142.62	0.40	161.13	0.81

Table 5.7: Validation of monthly SID measured by each satellite, compared with BSRN ground measurements. Acronyms: MAD: mean absolute difference; SD: standard deviance; RMSE: root mean squared error. Units: W / m².

Data source	Number of stations	Bias	MAD	SD	RMSE
GOES-E	13	1082.61	1082.61	80.97	171.87
Meteosat Prime	9	-80.76	80.76	17.00	30.29
GMS	7	109.19	574.80	117.69	108.96
MAGICSOL (all)	30	1299.41	1882.73	120.50	139.67

Unfortunately, much of the data produced demonstrates deviance from ground stations that is above the target accuracy, as table 5.6 shows. Meteosat Prime and GMS were able to best duplicate anomalies observed at their ground stations, while Meteosat IODC, surprisingly, had the lowest bias, RMSE and fraction of time steps above the validation threshold. Nonetheless, anomalies observed on the ground were correlated only by 0.4 with anomalies observed by the satellite. All in all, the MAGICSOL method was not able to consistently meet the accuracy targets outlined in table 1.1.

Table 5.7 shows the validation results for monthly averages. Meteosat IODC was omitted because only one ground station was within its viewing field, thus yielding only one comparison value. The results show the best performance by Meteosat Prime, followed by GMS. GOES-E performed very poorly, lowering the aggregated score of the MAGICSOL method across all satellites. The accuracy targets were also not met on the monthly scale. Notably, Meteosat Prime seemed to have a relatively consistent negative bias, as indicated by the negative bias and the MAD of similar magnitude, both for the daily and the monthly values. Both GOES-E and GMS demonstrated a more positive bias. This could be due to the different sensors used on the respective platforms.

5.4. SIS

The same CAL values used to produce the SID imagery also served as an input to produce the SIS imagery. Examples of typical days for each satellite can be seen in figures 5.24, 5.25, 5.26, 5.27 and 5.28.

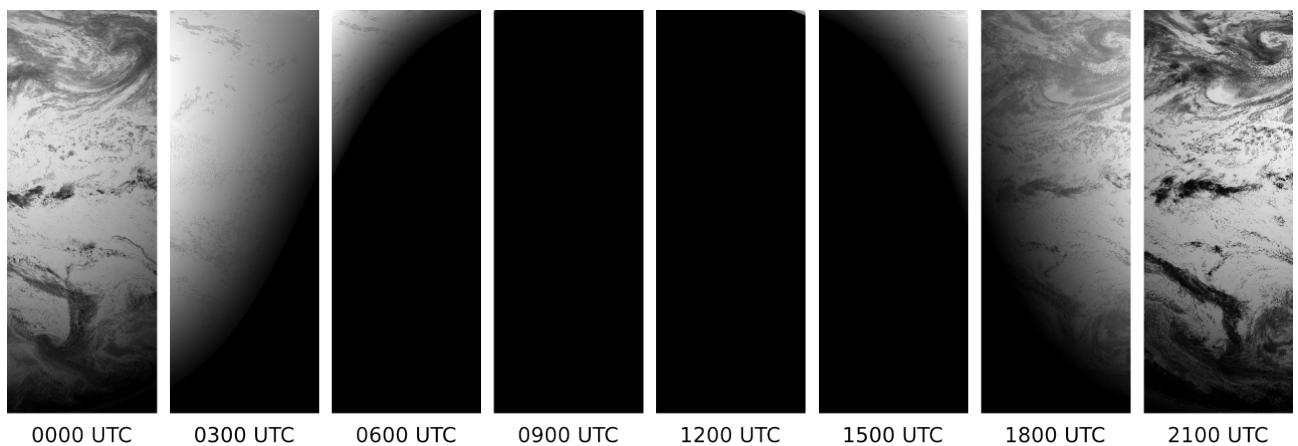

Figure 5.24: Normalized global irradiation values, computed with GOES-10 (GOES-W) scans on a typical day (163). Brighter pixels denote higher SID values.

The SID values generated with GOES-W data, shown in figure 5.24, show many of the same patterns as the SID data described in chapter 5.3. Contrast is much lower in these images, however, due to SIS's lower sensitivity to cloud cover as compared to SID.

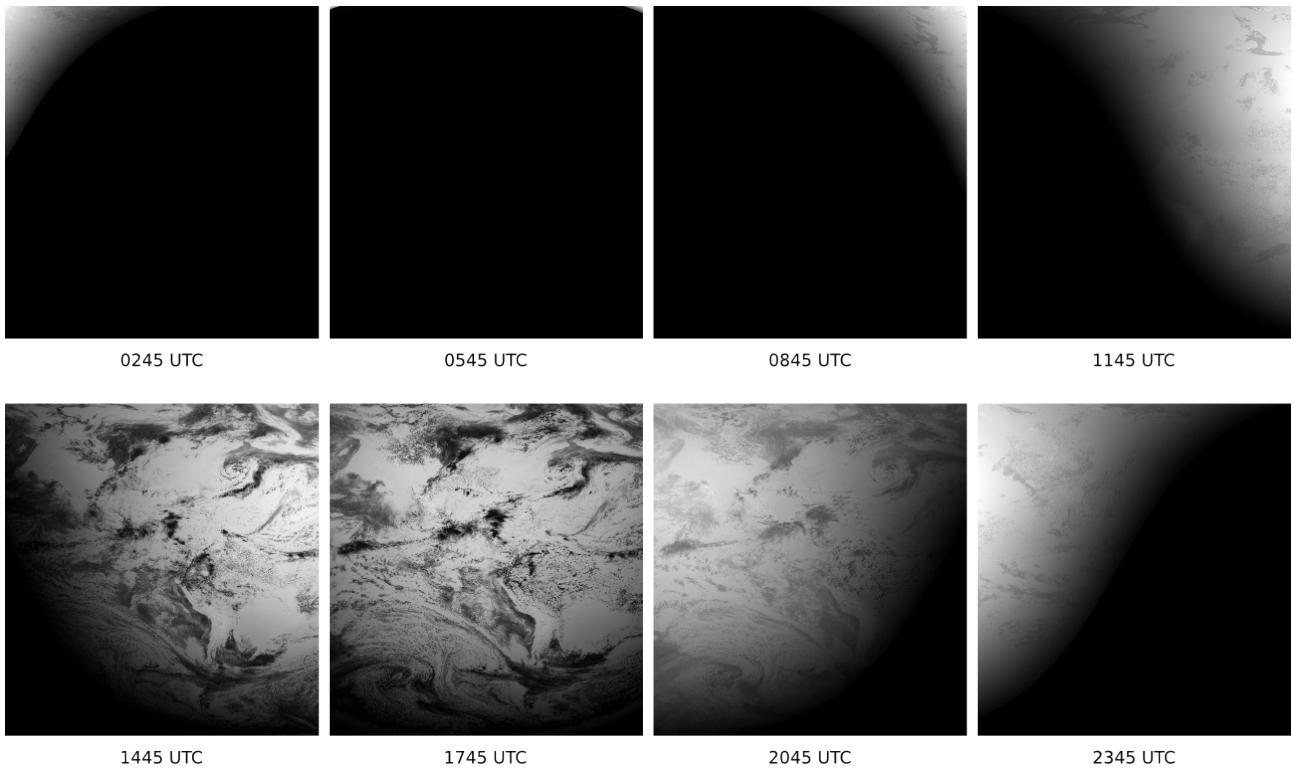

Figure 5.25: Normalized global irradiation values, computed with GOES-12 (GOES-E) scans on a typical day (176). Brighter pixels denote higher SID values.

Figure 5.25 shows SIS values generated from GOES-E. Note the continuing wash-out effect that is also observable in the CAL and SIS data generated from all GOES satellites.

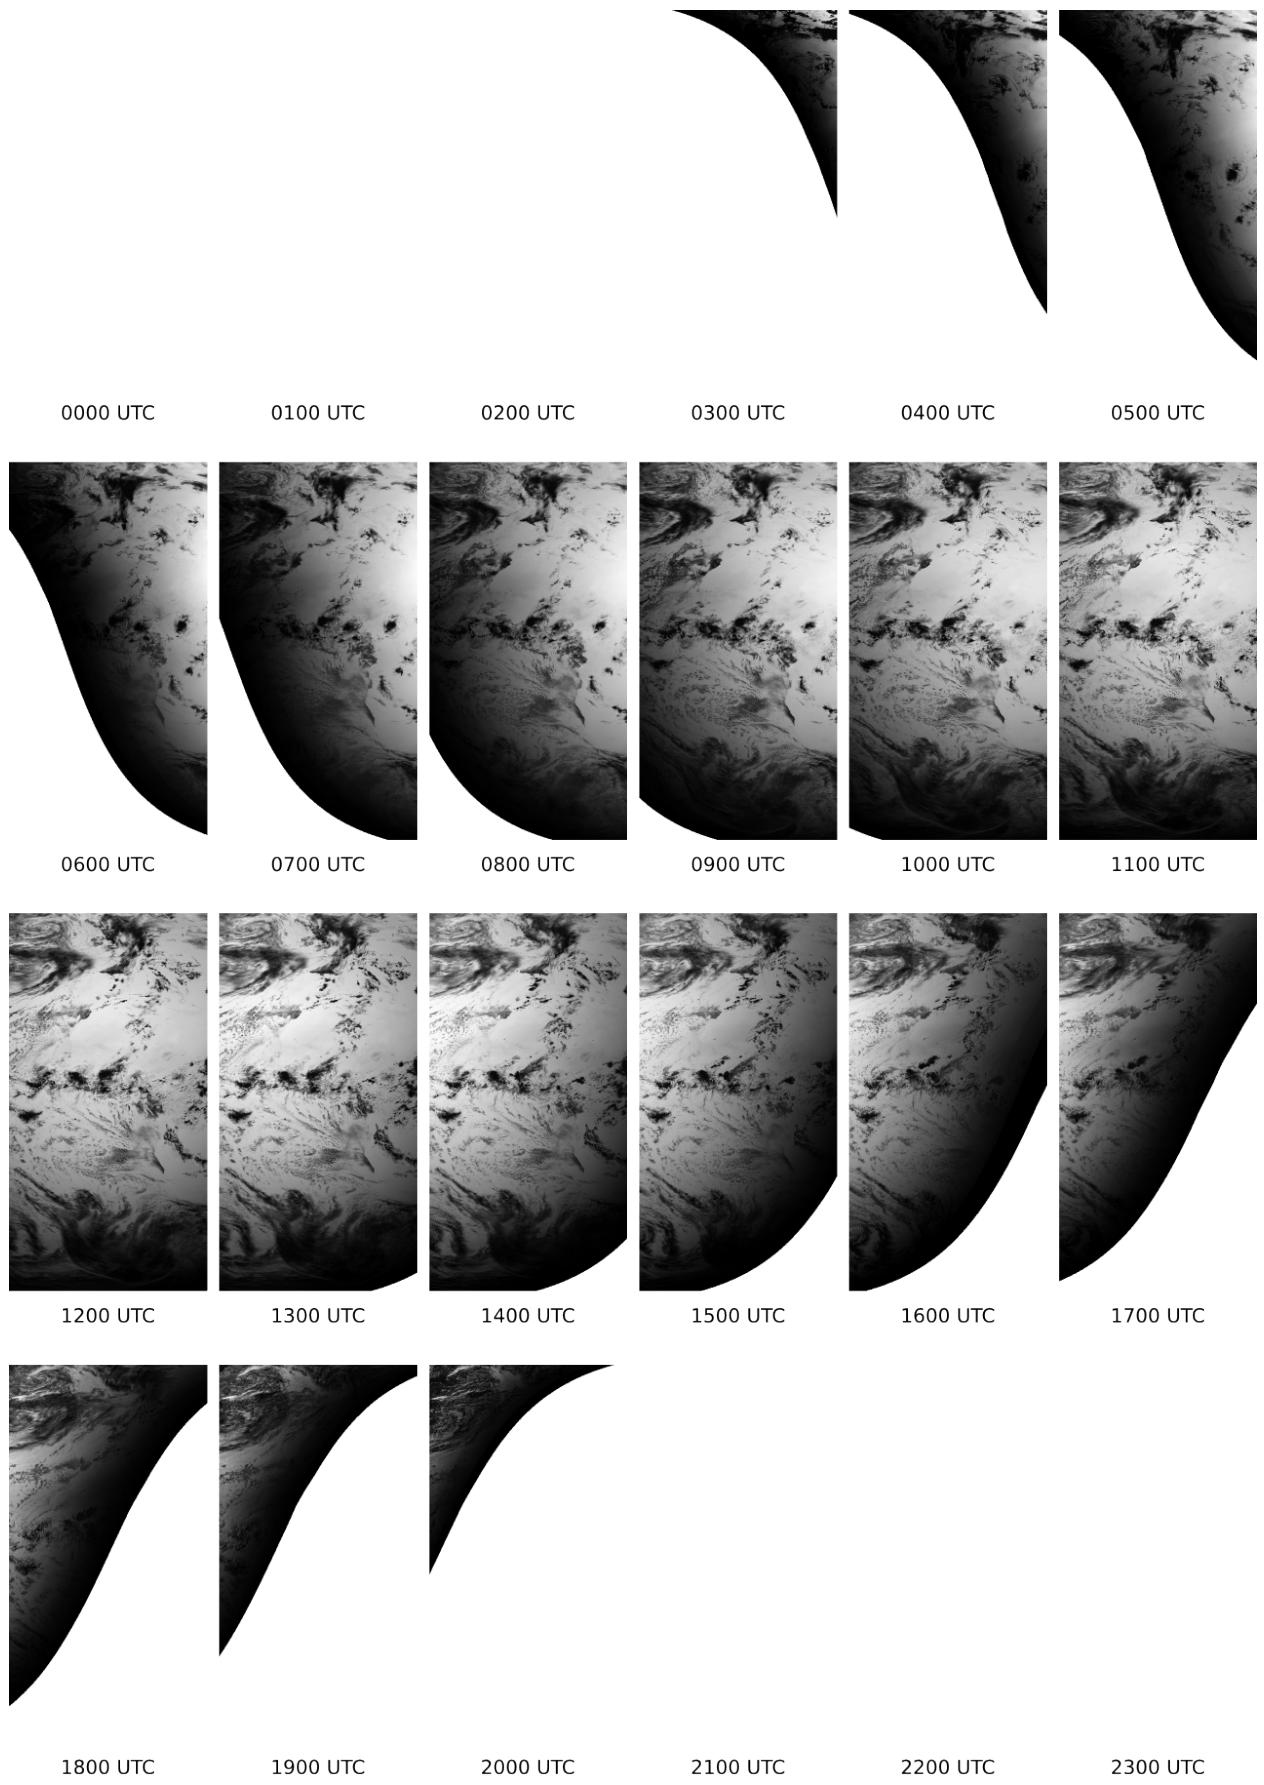

Figure 5.26: Normalized global irradiation values, computed with Meteosat Prime scans on a typical day (159). Brighter pixels denote higher SID values.

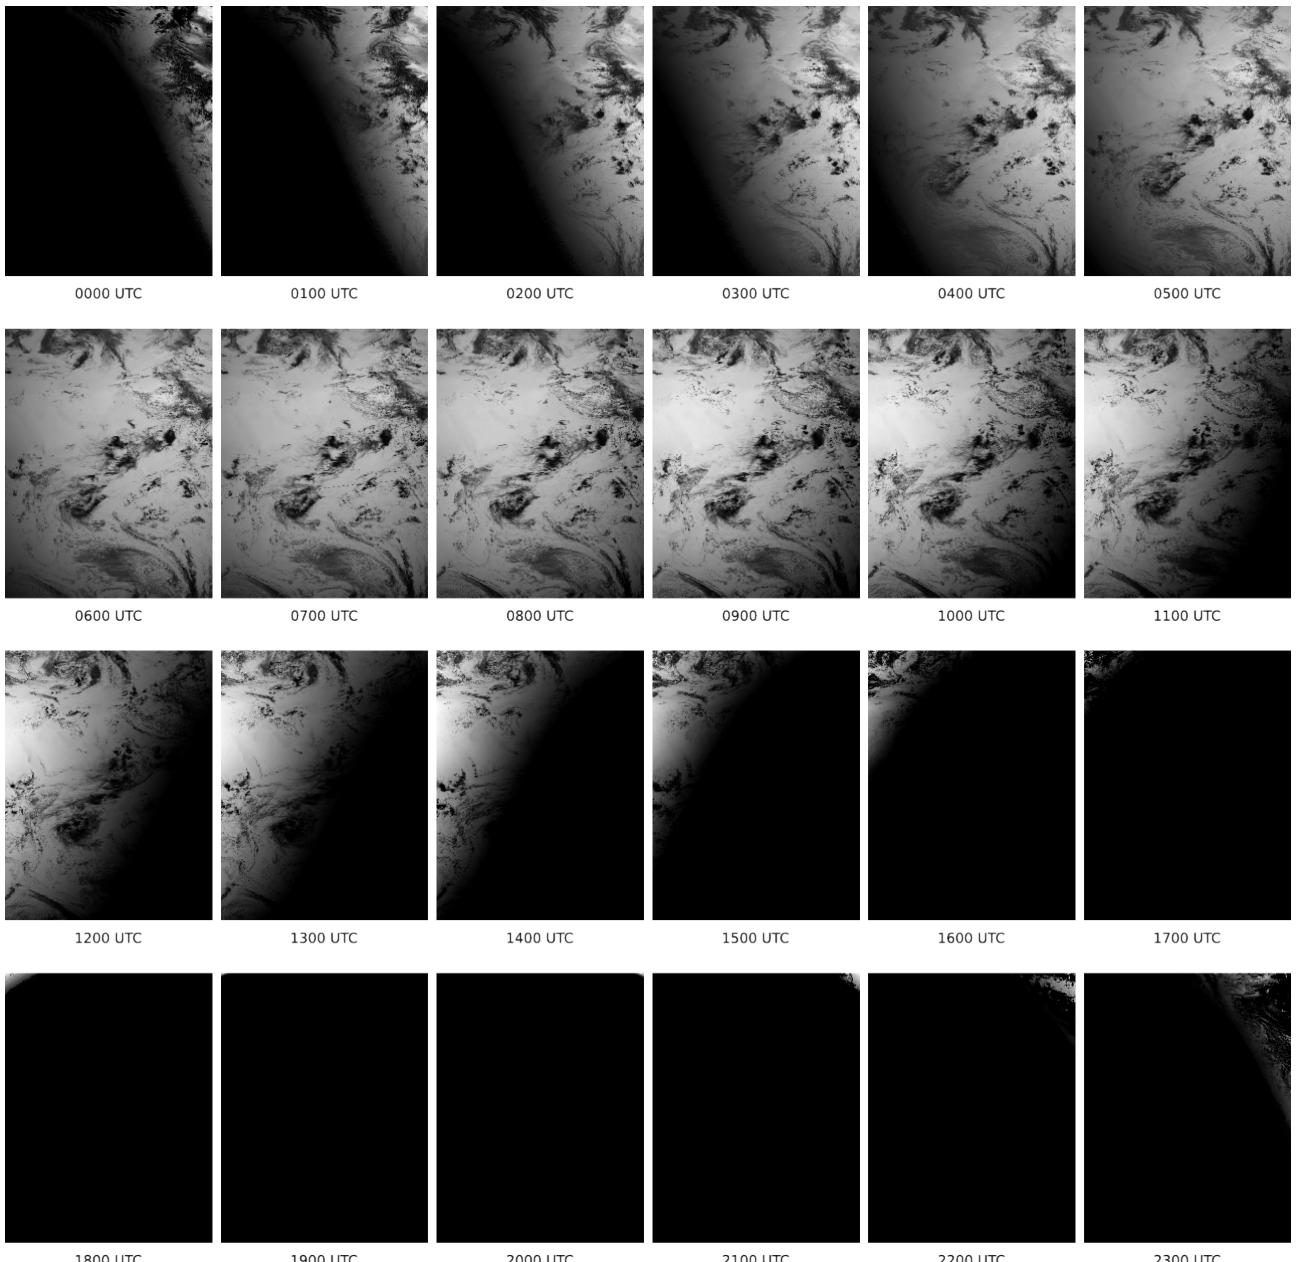

Figure 5.27: Normalized global irradiation values, computed with Meteosat IODC scans on a typical day (166). Brighter pixels denote higher SID values.

The SIS values generated by Meteosat Prime and Meteosat IODC in figures 5.26 and 5.27, respectively, demonstrate again the higher quality of the Meteosat data, especially in twilight zones.

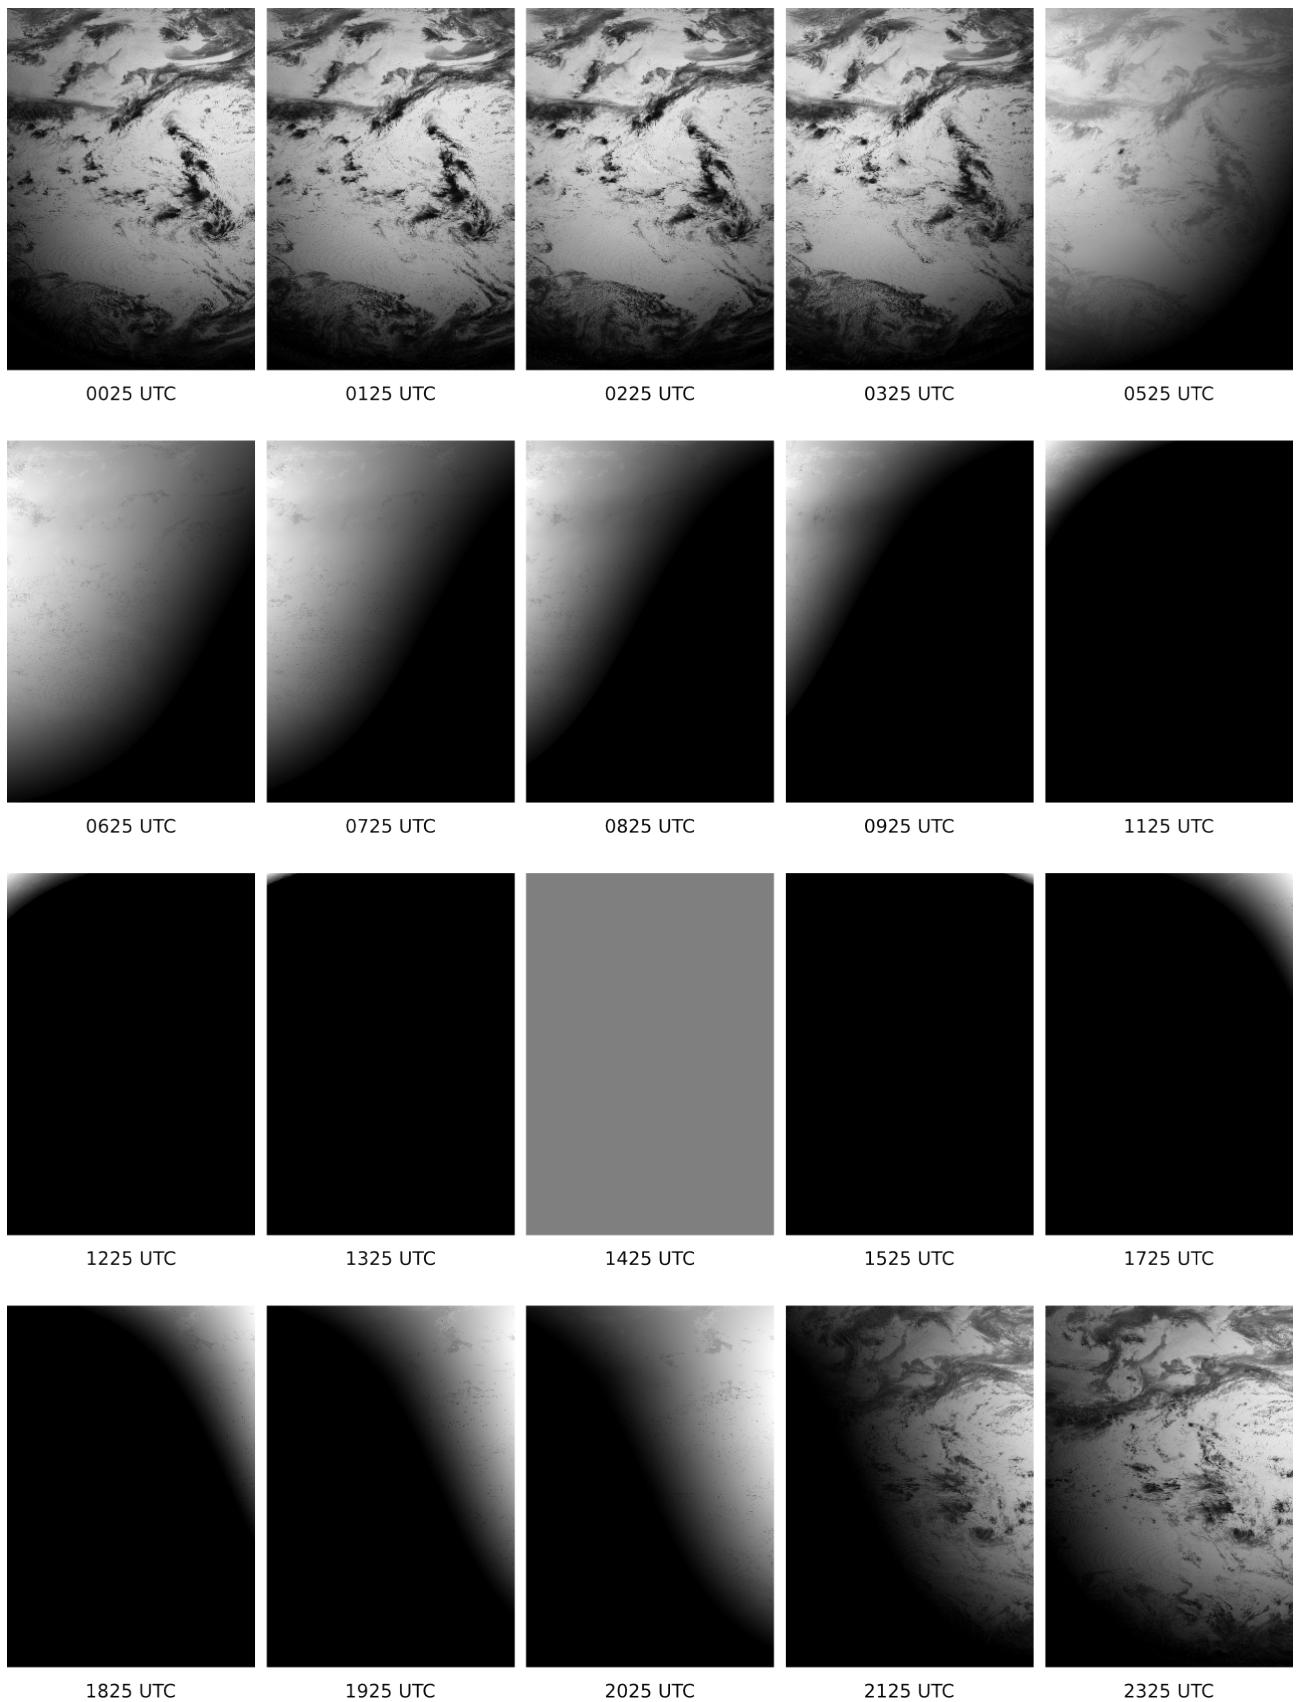

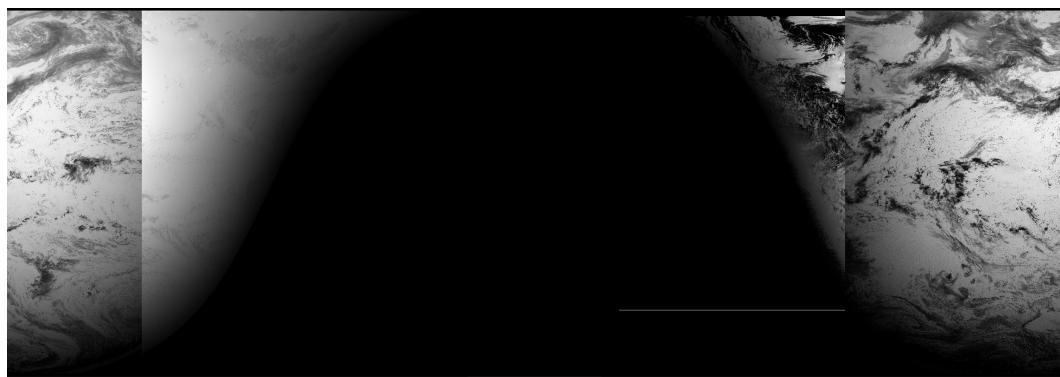

Figure 5.28: Normalized global irradiation values, computed with GOES-09 (GMS) scans on a typical day (157). Brighter pixels denote higher SID values.

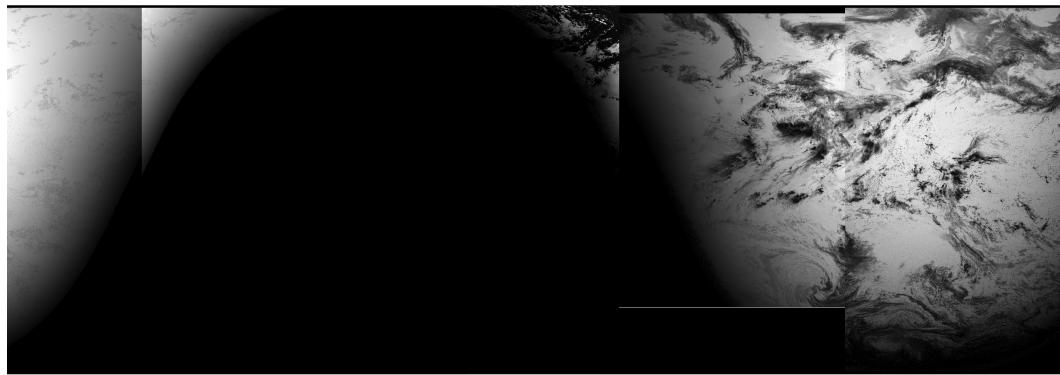

A typical day of SIS data generated by GMS is shown in figure 5.28. The gray image at

1425 UTC is an artifact of the image normalization and is not part of the generated data.

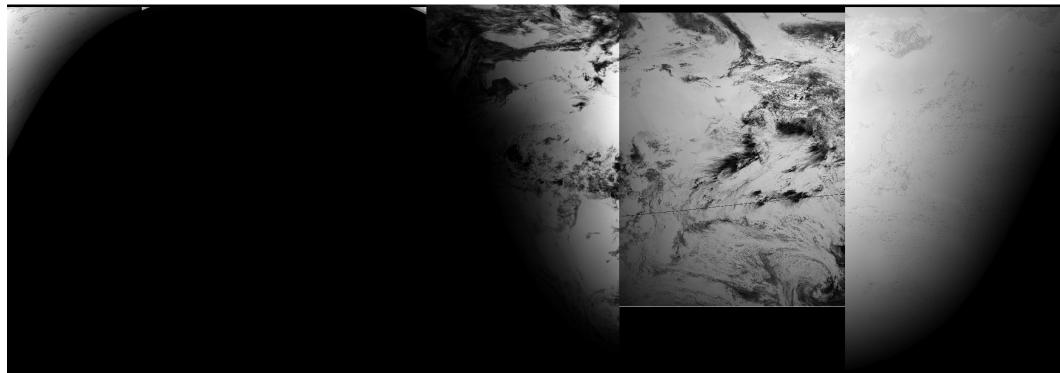

Combined global imagery can be found in figures 5.29 and 5.30.

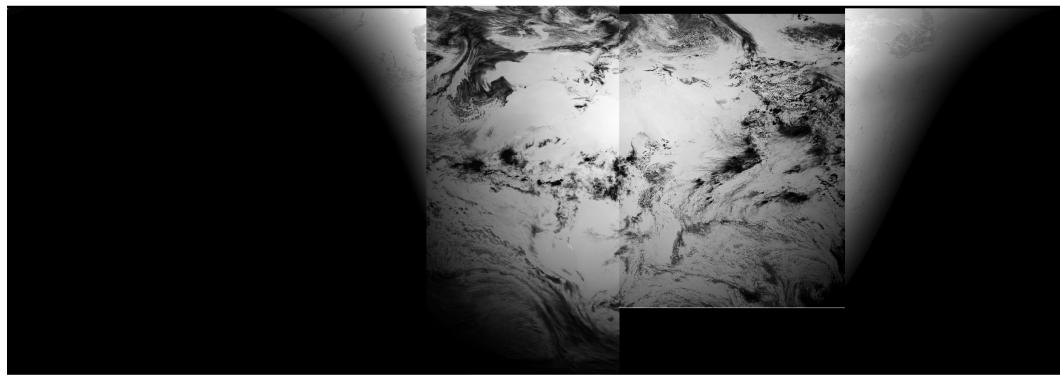

UTC 0000

UTC 0300

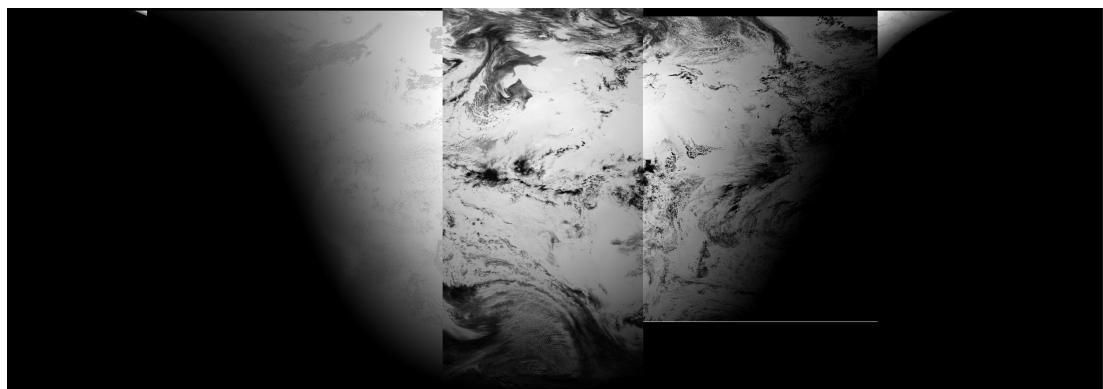

UTC 0600

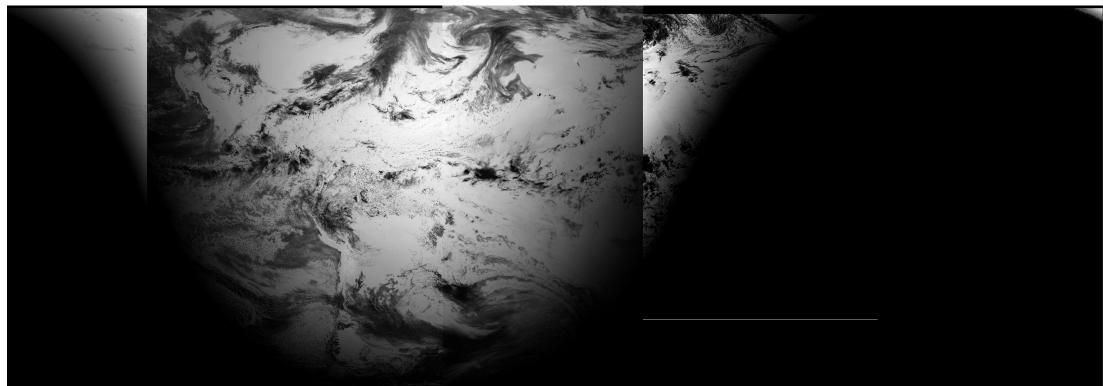

UTC 0900

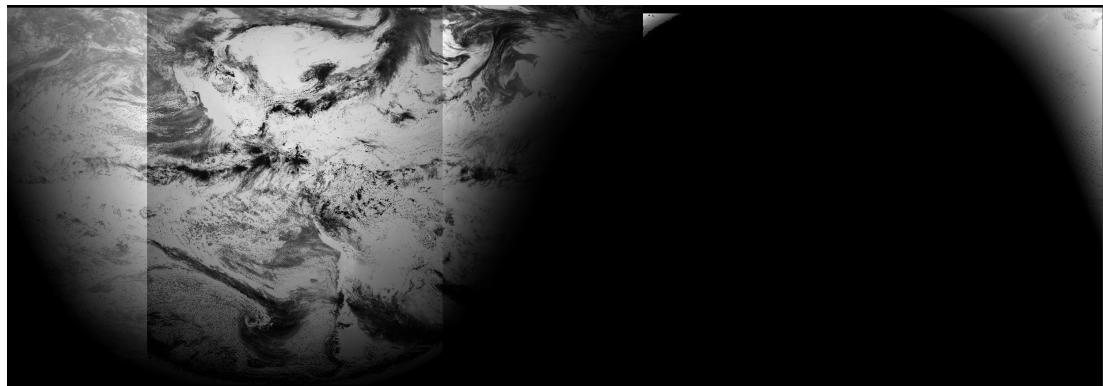

Figure 5.29: Hours 0000 – 0900 UTC on a typical day (171) of combined normalized SIS imagery using all geosynchronous satellites.

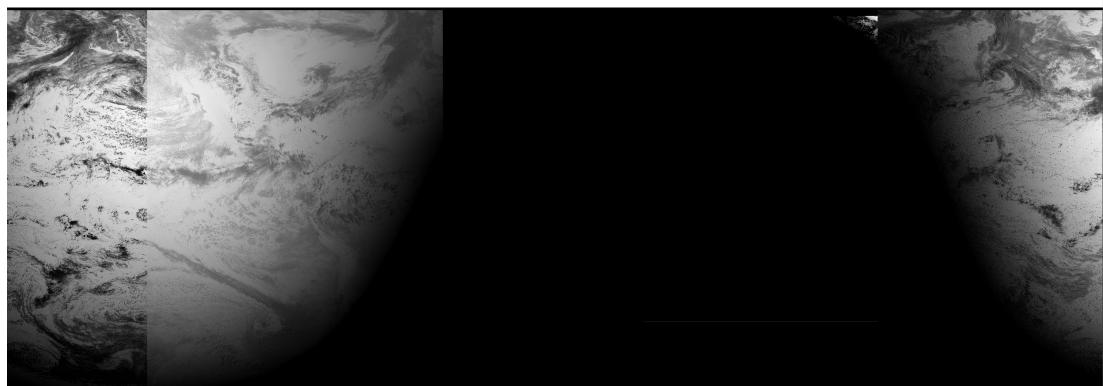

UTC 1200

UTC 1500

UTC 1800

UTC 2100

Figure 5.30: Hours 1200 – 2100 UTC on a typical day (171) of combined normalized SIS imagery using all geosynchronous satellites.

As was the case with the SID imagery, the global SIS pictures show that cloud formations and irradiation phenomena can be observed across satellite boundaries for single time steps. As was the case with SID, the low-zenith images observed by GOES satellites produce washed-out values, albeit less dramatically.

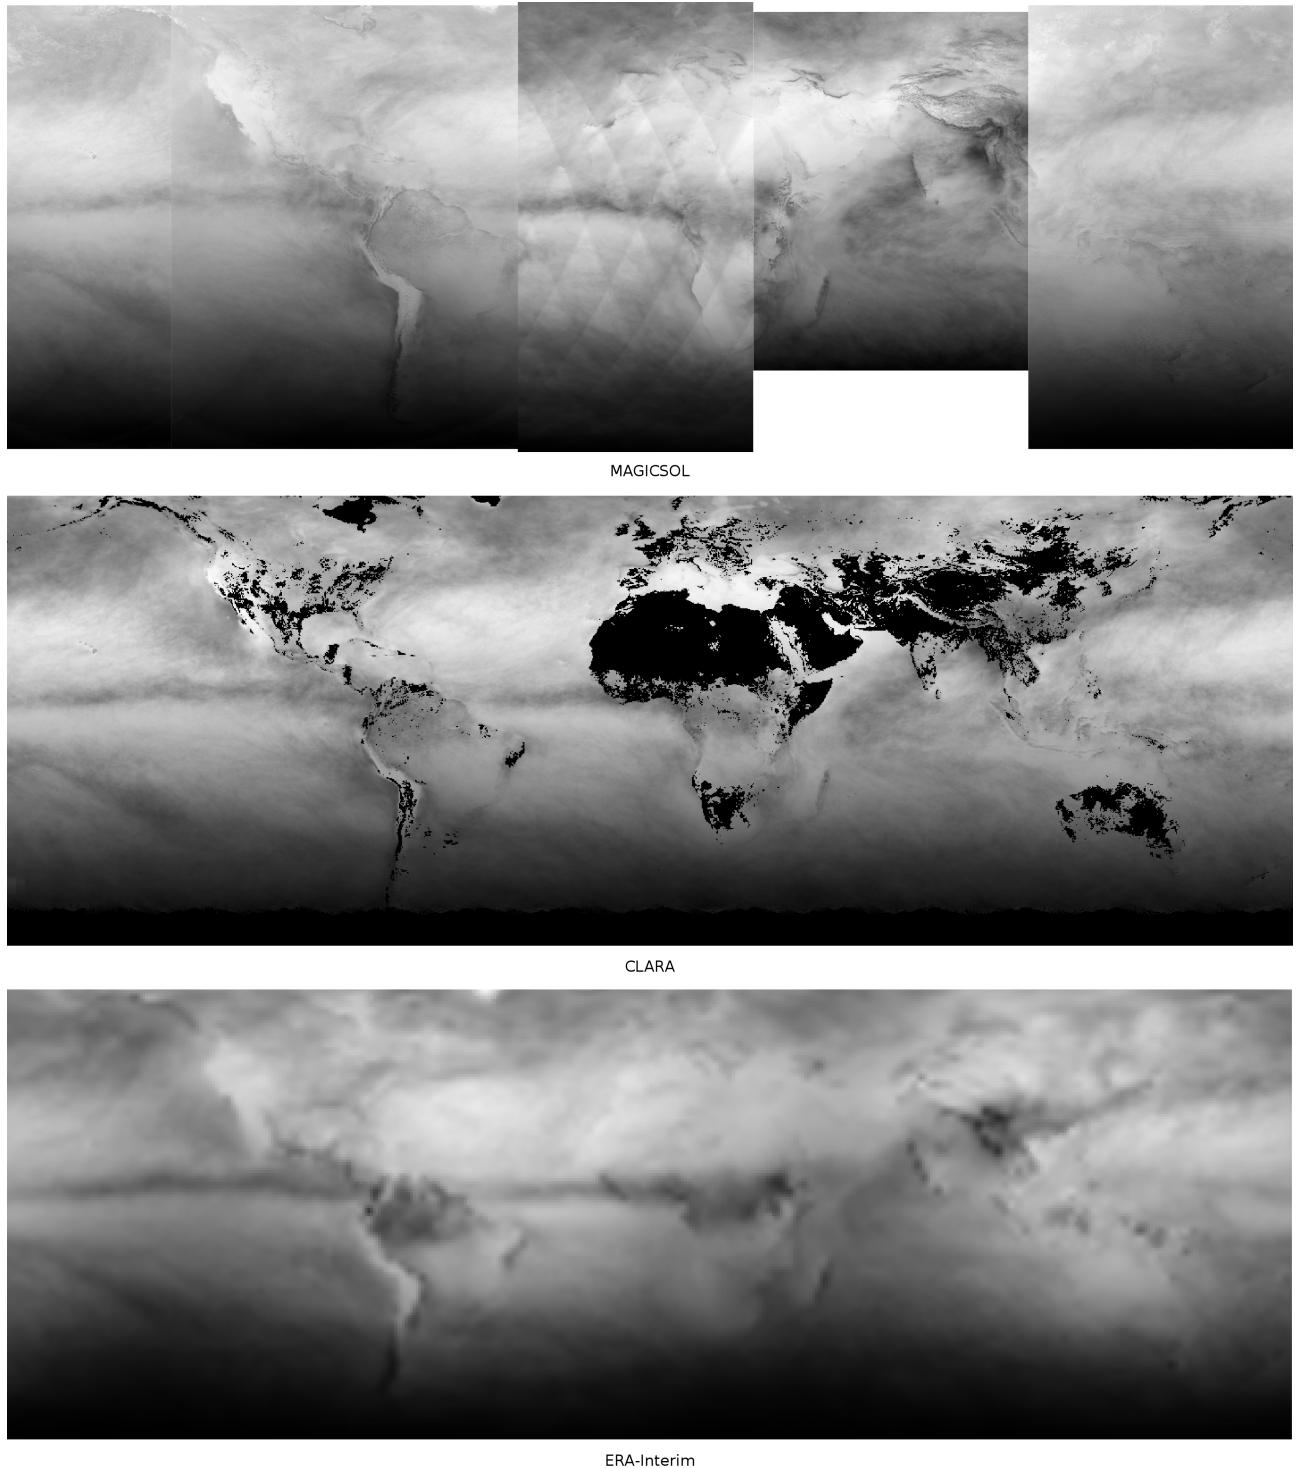

Figure 5.31: Monthly averages of SIS generated using (top to bottom): MAGICSOL, CLARA and ERA-Interim. Black areas in the CLARA map are where values are missing for the entire month.

Figure 5.31 shows the SIS monthly averages of each satellite produced using the MAGICSOL method, as well as averages from the other satellites. On all three images, the low values in the southern hemisphere make it clear that the average is for north-summer. Trade wind and monsoon clouds are also visible on all three images, as well as high irradiation over the Sonoran, Atacama and Kalahari Deserts. High cloud cover west of the Andes is also visible in all three images.

There are, however, several differences. First of all, the day-night borders visible in the SID imagery on all satellite averages except for Meteosat IODC are only visible for Meteosat Prime in the SIS averages, lending weight to the hypothesis that the stripes are indeed artifacts, in the case of GOES due to the wash-out effect and in the case of Meteosat Prime due to the cutoff of the day-night border during postprocessing. The day-night borders are not visible in the other data sets, which is to be expected in consideration of the data and techniques used to create them.

Several black areas are visible in the CLARA monthly averages. These are areas which were not measured during the entire month. This is normally due to high ground reflectance, which greatly lowers the accuracy of satellite measurements on those points. For this reason, such pixels and those with less than 20 observations per day are removed from the CLARA data set (Trentmann, Müller, et al. 2012b). An overview of all missing measurements over the entire month is provided in figure 5.32.

Figure 5.32: Monthly averages of SIS as generated from CLARA data. Areas in which at least one daily value is missing are colored black.

The ERA-Interim data has no missing data, but its horizontal resolution is much lower than that of both the MAGICSOL and the CLARA data.

A comparison of the overlap views by each adjacent satellite can be found on figures 5.33,

5.34, 5.35 and 5.36.

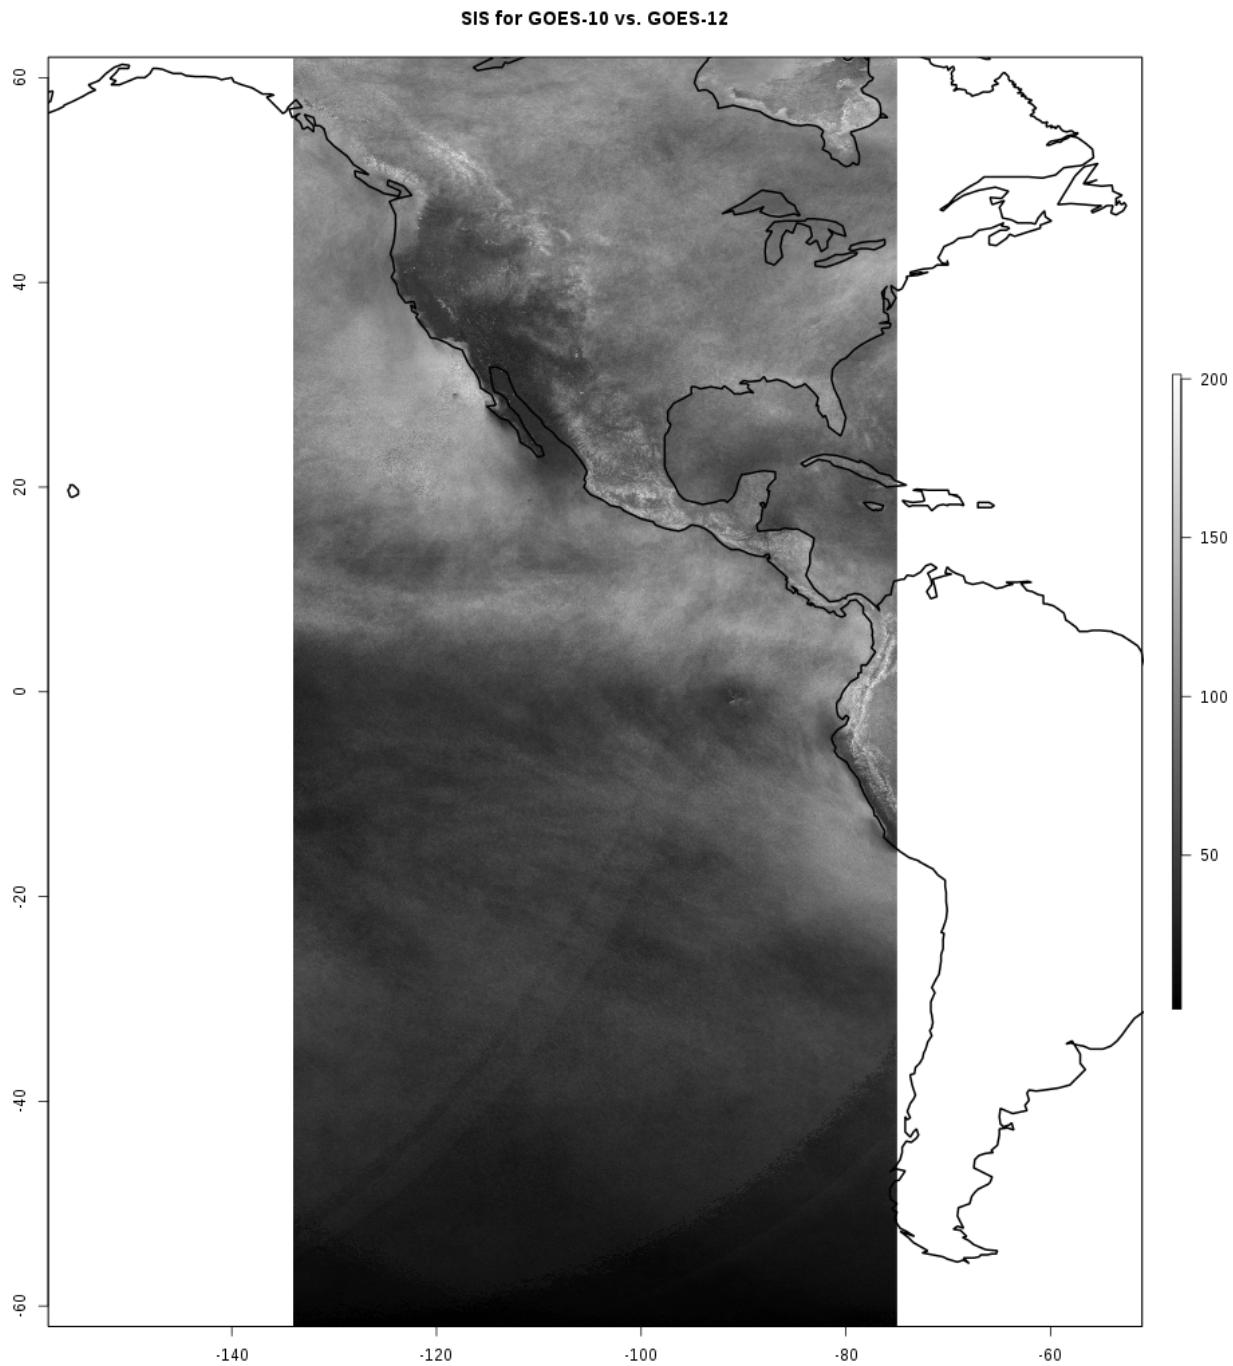

Figure 5.33: Deviance in monthly means of SIS computed by GOES-W and GOES-E, measured in W / m^2 .

Figure 5.33 shows the deviation between GOES-10 and GOES-12 SIS measurements. The agreement is generally higher than for SID, which is to be expected given the lower sensitivity of SIS values to cloud cover. Deviance is quite low, as is also demonstrated numerically in table 5.8.

Table 5.8: Differences in simultaneous observations obtained by GOES-W and GOES-E. Units are W / m².

Minimum	Maximum	Standard deviance	Mean
0.00	1084.34	70.16	68.49

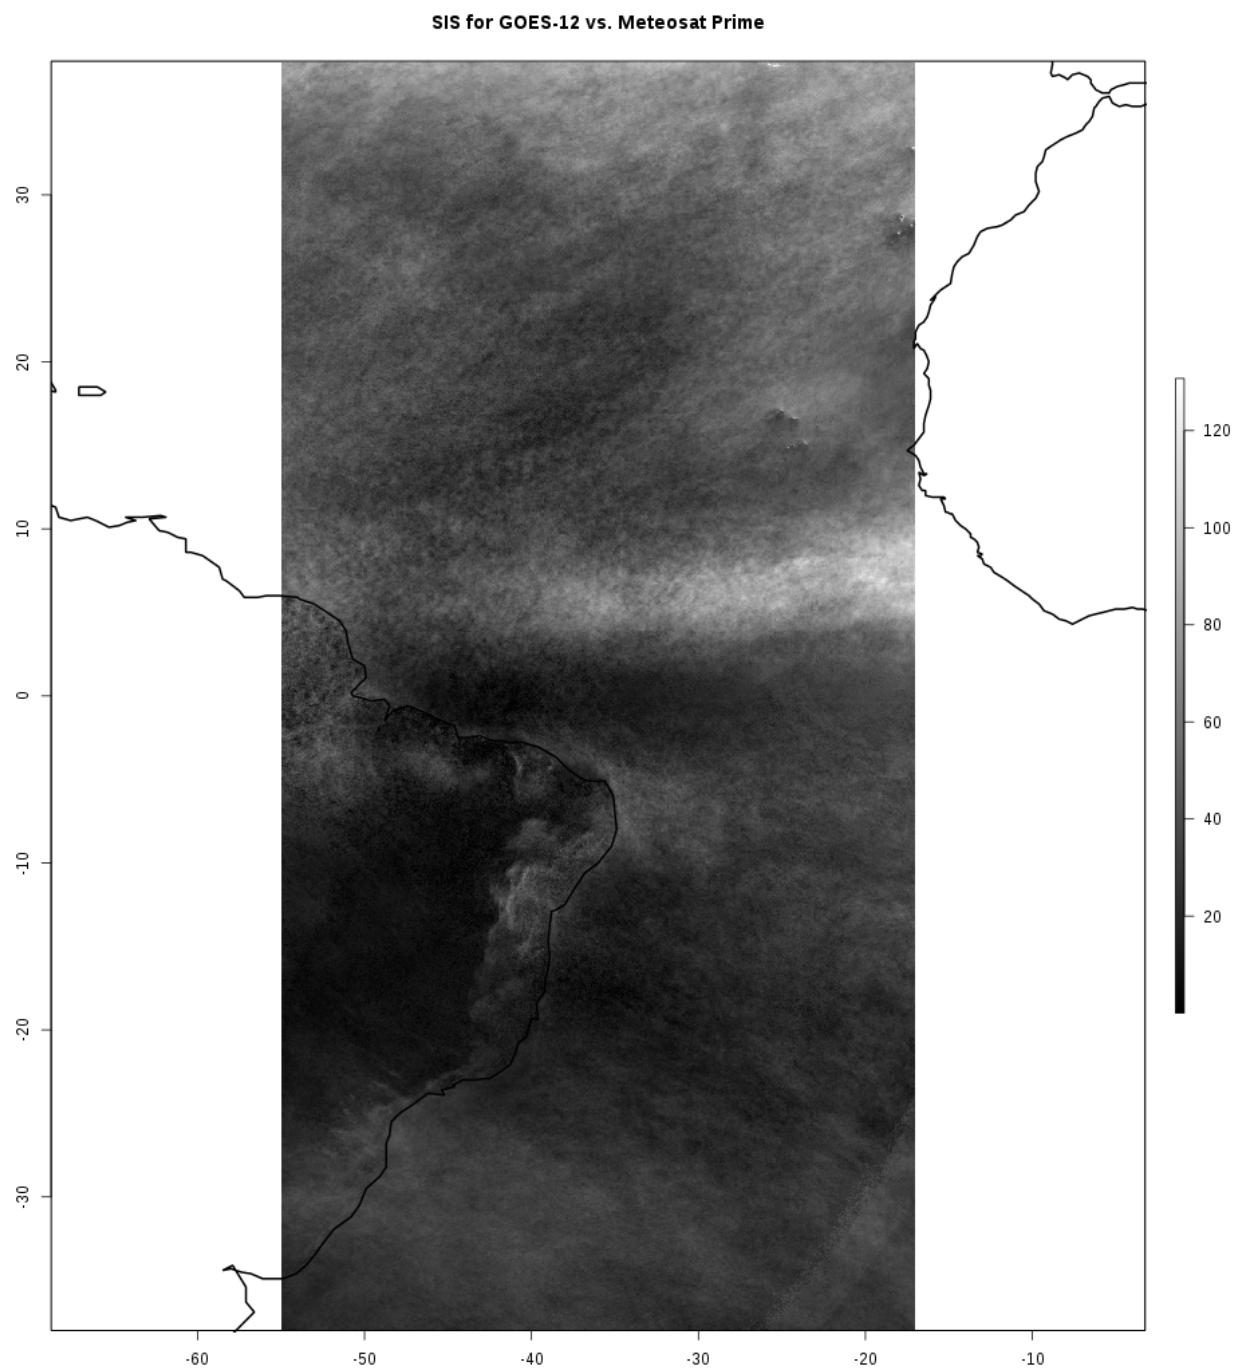

Figure 5.34: Deviance in monthly means of SIS computed by GOES-E and Meteosat Prime, measured in W / m².

Figure 5.34 shows very high agreement between GOES-12 and Meteosat Prime SIS

values. Interestingly, the lowest variability was over the eastern coast of South America, while high variability could be observed directly south of the trade winds. However, these values only are high in comparison to the other pixels in the scene. On a whole, the deviance between both SIS values was very small, as is shown in table 5.9.

Table 5.9: Differences in simultaneous observations obtained by GOES-E and Meteosat Prime. Units are W / m².

Minimum	Maximum	Standard deviance	Mean
0.00	157.41	18.30	35.39

SIS for Meteosat Prime vs. Meteosat IODC

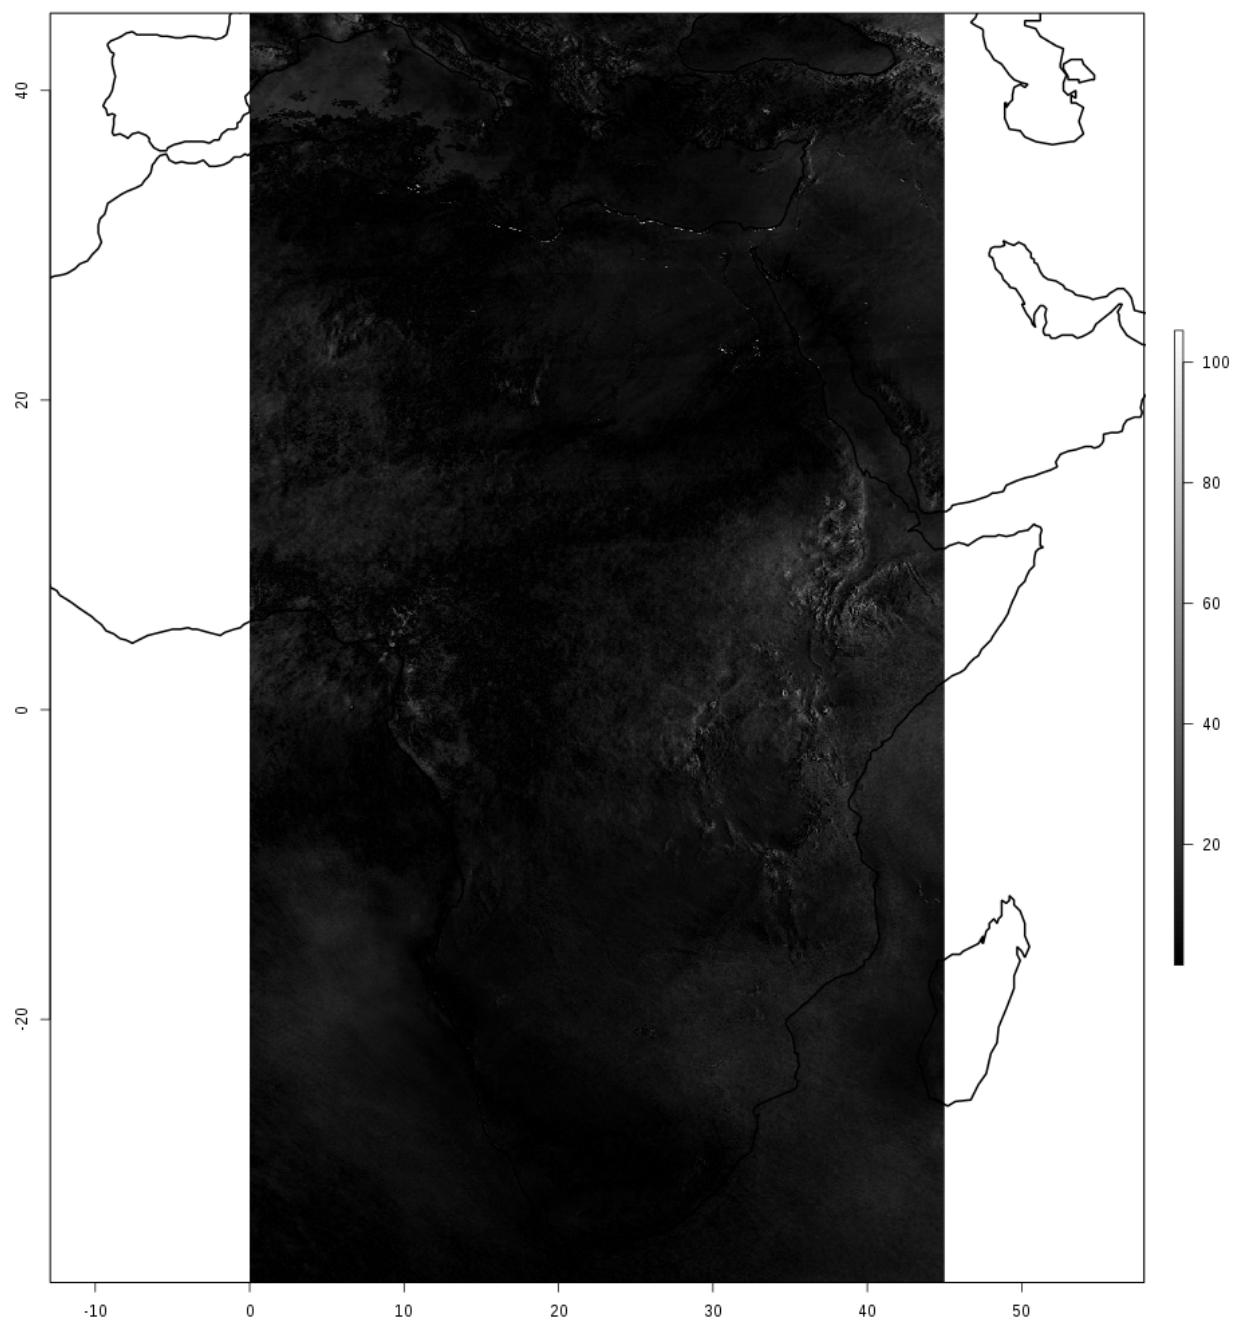

Figure 5.35: Deviance in monthly means of SIS computed by Meteosat Prime and Meteosat IODC, measured in W / m^2 .

Extremely low variability was found between Meteosat Prime and Meteosat IODC. As table 5.10 shows, this can be confirmed numerically.

Table 5.10: Differences in simultaneous observations obtained by Meteosat Prime and Meteosat IODC. Units are W / m².

Minimum	Maximum	Standard deviance	Mean
0.00	115.74	4.98	6.53

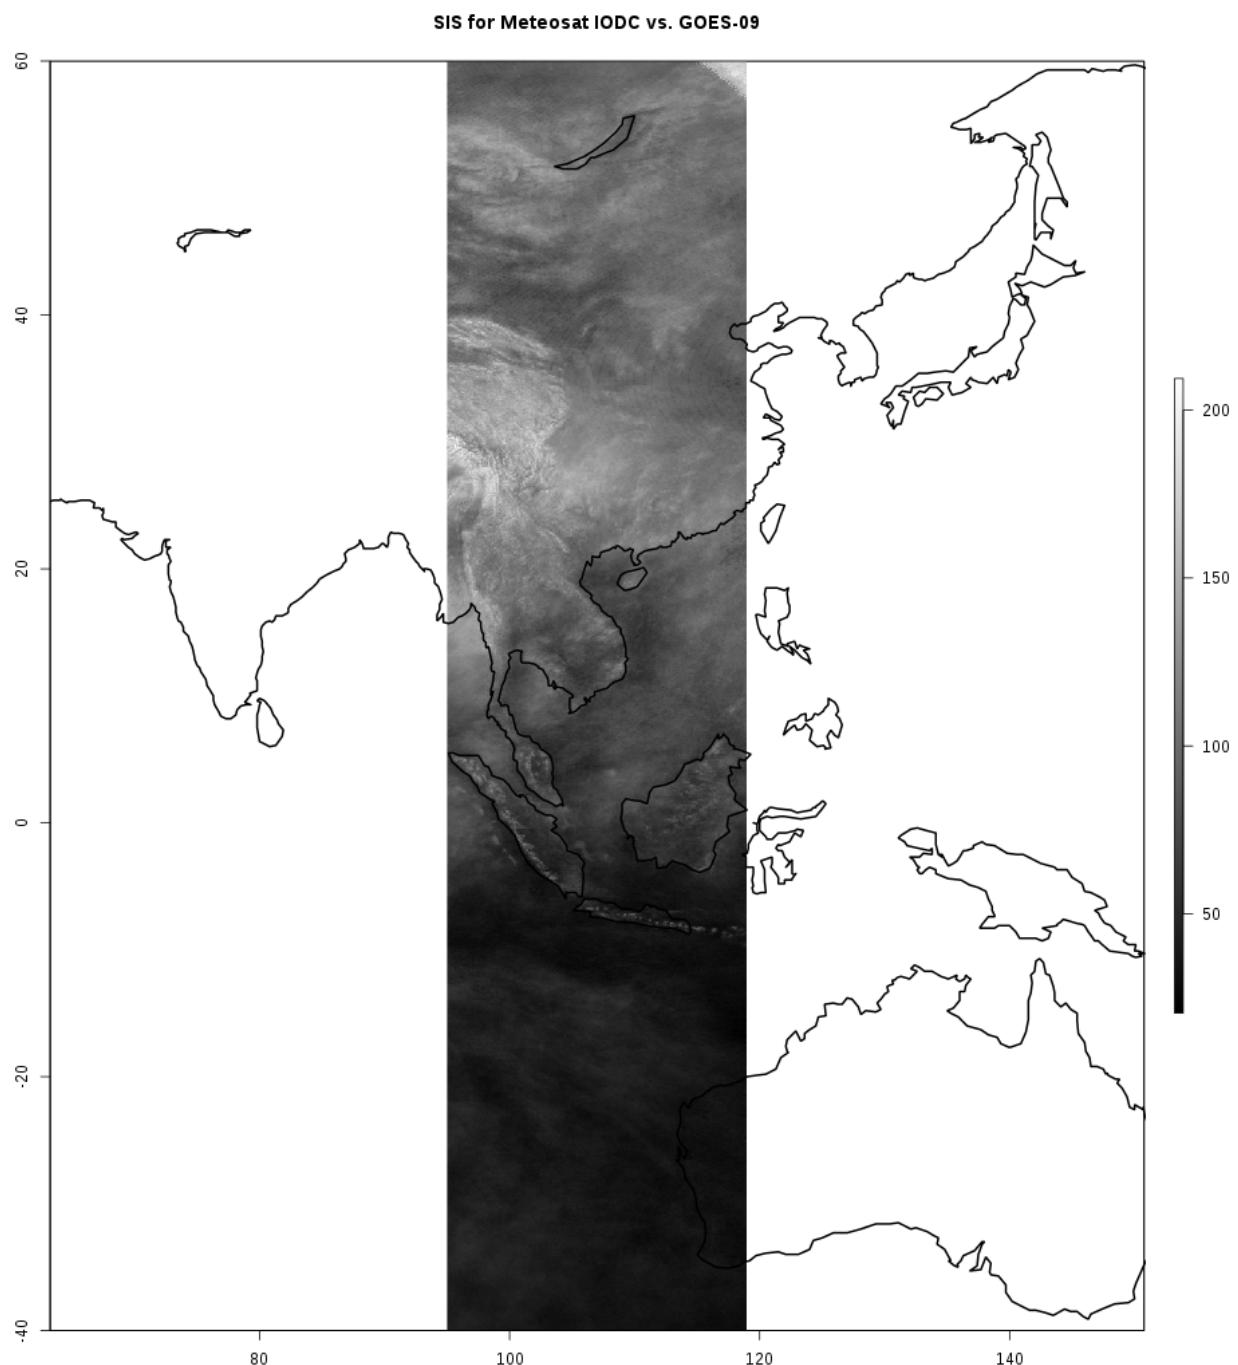

Figure 5.36: Deviance in monthly means of SIS computed by Meteosat IODC and GMS, measured in W / m².

In comparison to the agreement between the Meteosat satellites, Meteosat IODC and

GMS varied quite a bit, as is shown in figure 5.36. However, this level of agreement is still very high, as shown in table 5.11.

Table 5.11: Differences in simultaneous observations obtained by Meteosat IODC and GMS. Units are W / m².

Minimum	Maximum	Standard deviance	Mean
19.74	212.03	34.45	76.06

Figures 5.37 and 5.38 show a comparison of the values computed and the corresponding station values, organized by data source.

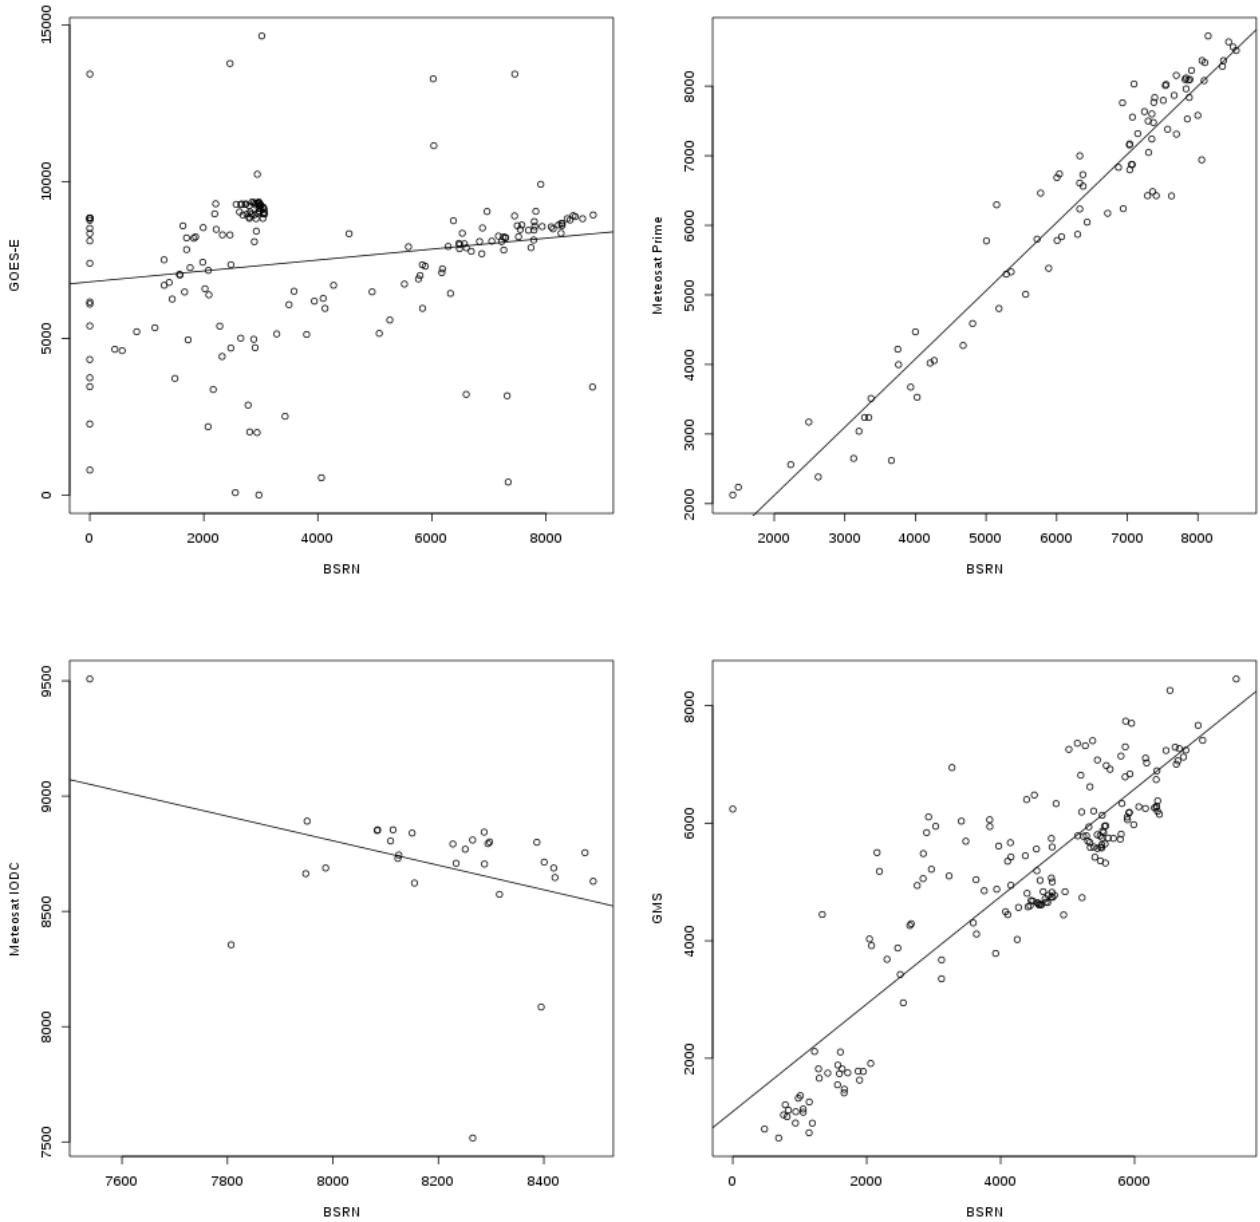

Figure 5.37: Computed SIS values in daily sums of Wh / m^2 plotted against corresponding ground station measurements for each satellite. Clockwise from the top left: GOES-E, Meteosat Prime, Meteosat IODC, GMS.

As figure 5.37 shows, Meteosat Prime seems to have performed best, followed by GMS. GOES-E shows worse scores, whereas the anomalous BSRN values noted in chapter 5.3 should also be taken into account. Meteosat IODC performed the worst, but in reality the number of validation samples is too small to conclusively say that the MAGICSOL method does not work with that satellite.

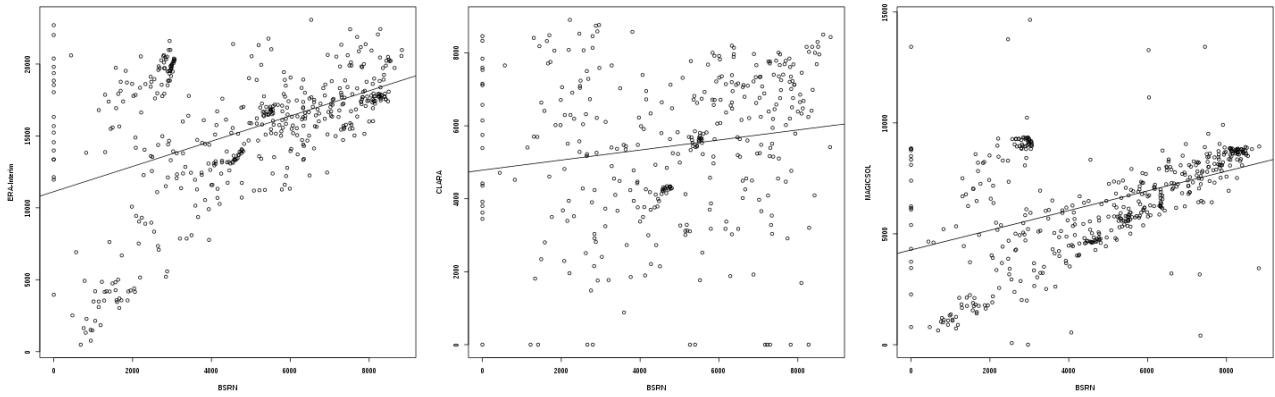

Figure 5.38: Computed SIS values in daily sums of Wh / m^2 plotted against corresponding ground station measurements from each data source. From left to right: ERA-Interim, CLARA, MAGICSOL.

Figure 5.38 shows the combined scores of each data source against the BSRN ground stations. All data sources demonstrate a wide spread of values, whereas MAGICSOL data shows the highest consistency with the validation data, followed by CLARA. In all data sources, anomalous BSRN station data can be observed in which no SIS was measured over the course of several days.

Table 5.12: Validation of daily SIS measured by each data source, compared with BSRN ground measurements. Acronyms: MAD: mean absolute difference; SD: standard deviance; AC: anomaly correlation; RMSE: root mean squared error; Frac: Fraction of time steps above validation threshold. Units: W / m^2 , for AC and Frac %.

Data source	Number of stations	Bias	MAD	SD	AC	RMSE	Frac
GOES-E	13	144.64	159.20	134.31	0.19	197.13	0.88
Meteosat Prime	9	1.43	15.73	19.77	0.97	19.71	0.20
Meteosat IODC	1	21.04	23.98	17.95	0.36	27.46	0.40
GMS	7	30.57	32.64	39.95	0.87	50.21	0.39
ERA-Interim	31	438.92	438.99	171.25	0.46	471.08	0.99
CLARA	23	22.84	85.06	117.88	0.16	119.91	0.68
MAGICSOL (all)	30	67.29	76.39	105.52	0.45	125.05	0.54

Table 5.13: Validation of monthly SIS measured by each satellite, compared with BSRN ground measurements. Acronyms: MAD: mean absolute difference; SD: standard deviance; RMSE: root mean squared error. Units: W / m².

Data source	Number of stations	Bias	MAD	SD	RMSE
GOES-E	13	907.56	907.96	104.35	161.73
Meteosat Prime	9	4.30	15.30	7.48	6.28
GMS	7	183.41	183.41	31.93	42.24
ERA-Interim	31	7474.99	7474.99	141.71	460.70
CLARA	23	251.75	580.93	74.44	74.09
MAGICSOL (all)	30	1116.70	1127.70	86.97	106.93

Tables 5.12 shows the results of the daily validation. As could be expected in light of the data presented before these tables, Meteosat Prime performed the best, with a daily bias well within the target accuracy. 80% of its measurements were within the target accuracy. Meteosat Prime was followed in accuracy by Meteosat IODC and GMS. Meteosat IODC had low bias, MAD, SD and RMSE scores, but, as was in the case of the SID data, AC was also very low. GMS had scores similar to Meteosat IODC, but its AC was much higher. The sample available to validate GMS was also much larger than that for Meteosat IODC, producing more trustworthy values for GMS. CLARA and GOES-E were quite similar in daily validation values, although more CLARA values were within the accuracy targets than was the case for GOES-E. The worst values were produced by ERA-Interim. The combined scores for all data produced with the MAGICSOL method were better than for ERA-Interim and CLARA, showing that, on a whole, MAGICSOL performed the best.

Table 5.13 shows the results of the monthly validation. As was the case with the daily values, Meteosat Prime performed best, followed by GMS. CLARA performed better than GOES-E, and ERA-Interim had the worst scores. On a whole, CLARA outperformed MAGICSOL on a monthly level. This is most likely due to the low scores produced by GOES-E – the daily scores for MAGICSOL as a whole were computed per station, per day, whereas the monthly scores were computed once per station for the entire month. Because GOES-E had 13 validation stations, its score was the strongest among the satellites used in the monthly validation of the MAGICSOL data.

5.5. Summary

The previous chapters show that the MAGICSOL method performed quite well, also with

the GOES satellite series. This confirms the hypothesis that the method is capable of producing superior data than is currently available from other sources. Its validation scores during the test time frame are higher than those of alternative data sources, and it is capable of producing data with a much higher spatial resolution than similar data sets (0.01° , as compared to 0.25° for CLARA and 0.75° for ERA-Interim).

Before the MAGICSOL method can be used to produce high-quality global CDRs for long time series, however, some issues would have to be addressed: Validation, temporal resolution and the twilight effect.

As demonstrated in chapter 4, validation data for solar irradiation is difficult to find, and validation cloud albedo data is simply unavailable. For this reason, station measurements collected by BSRN were used for validation in this study. The BSRN data has a high quality and is mostly free of errors, as can be seen in the typical station time series shown in figure 5.39.

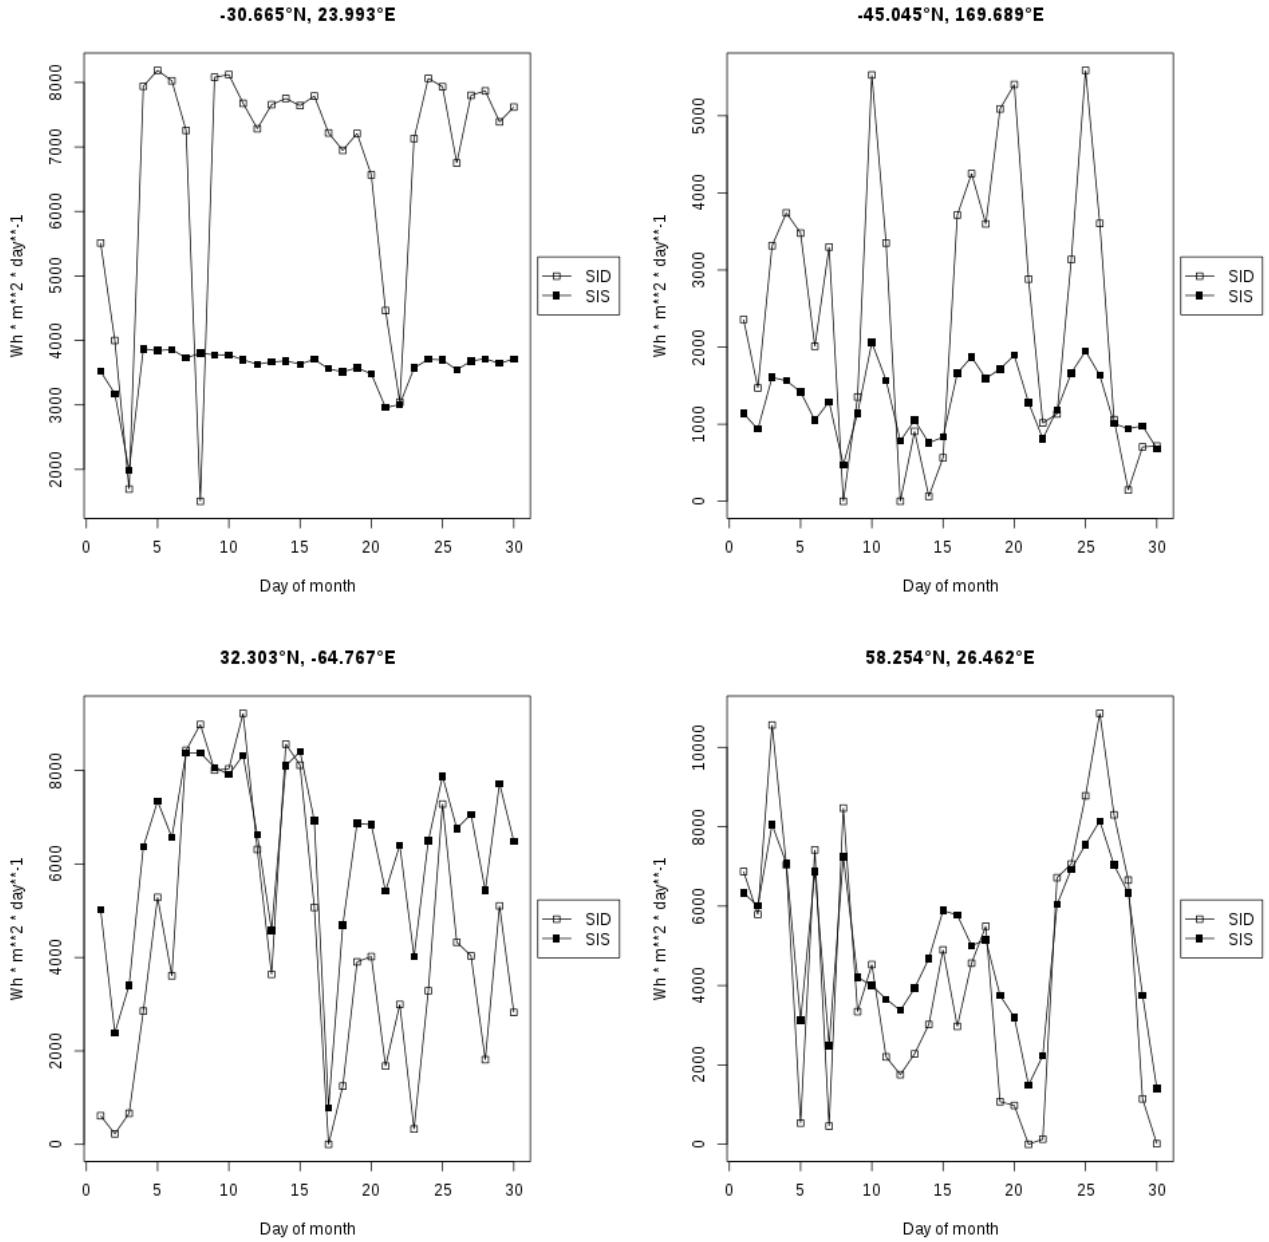

Figure 5.39: Wh / m^2 received at four BSRN stations during the test time period.

For the four stations shown, SID and SIS fluctuate to a certain degree and also demonstrate a mutual correlation. This is to be expected. However, some stations showed erroneous values that would have to be cleansed from the data set for an accurate, comprehensive validation. Examples of such measurements can be seen in figure 5.40.

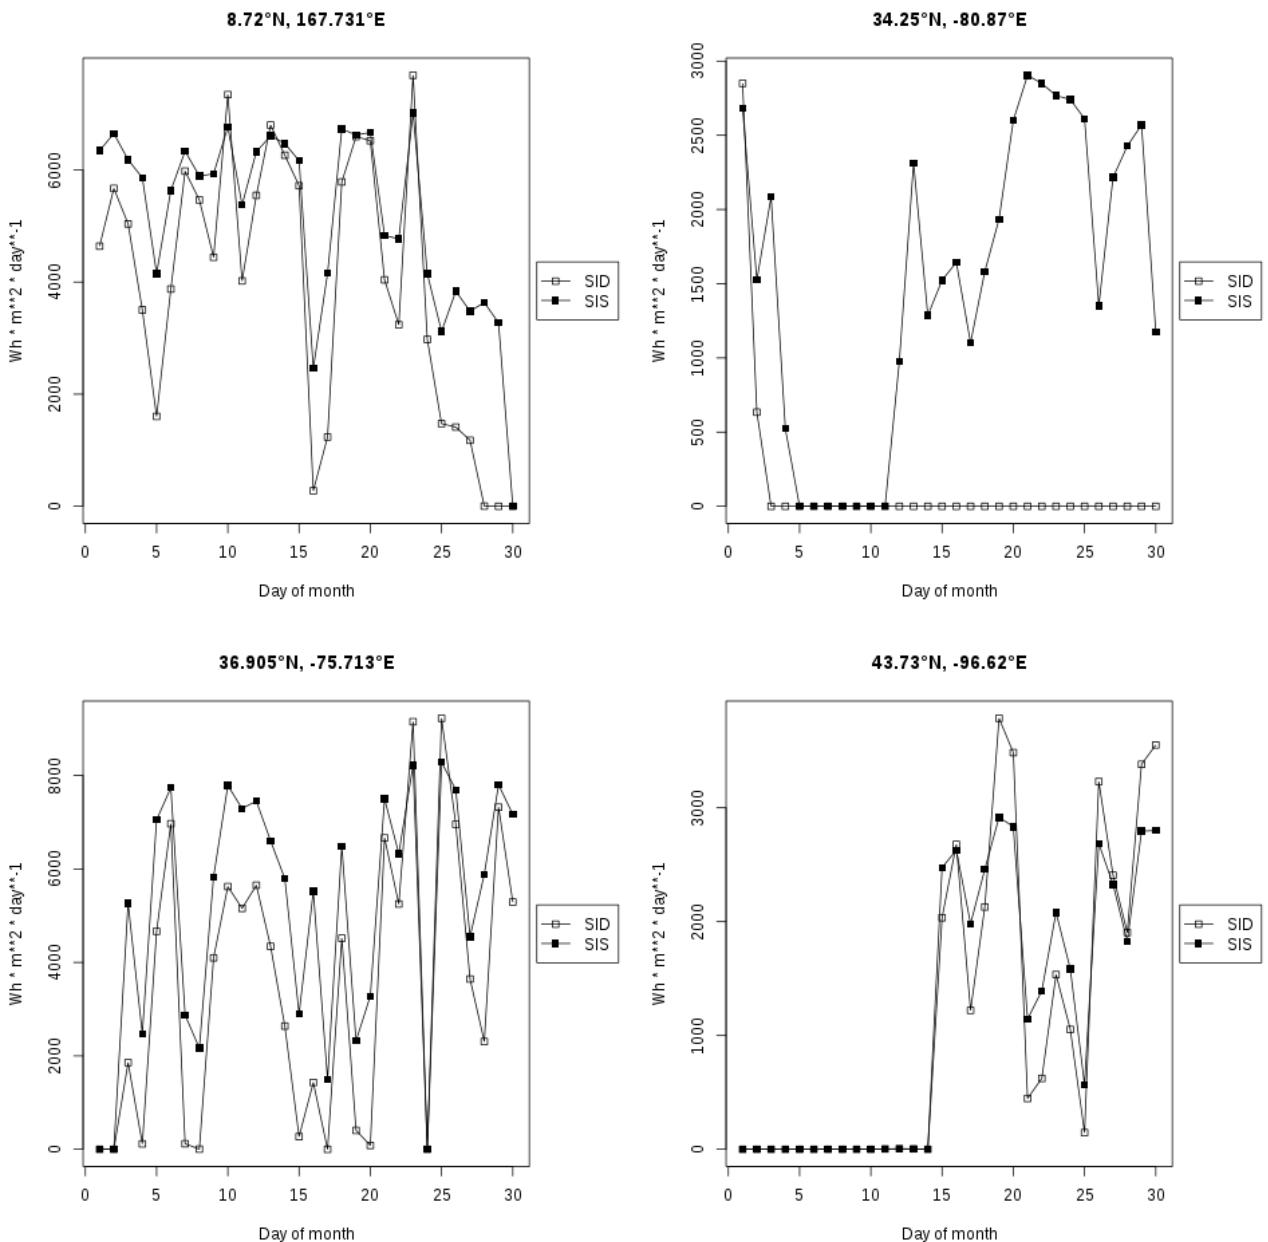

Figure 5.40: Wh / m² received at four BSRN stations during the test time period.

As the figure shows, these stations contain anomalies that are instantly apparent. It is impossible that an unshadowed pyranometer should receive 0 SIS for an entire day, let alone for several consecutive days, unless it is located at one of the poles in winter. If a large data set were to be validated, such errors, as well as possible errors that are not apparent after a first-look analysis, would have to be removed from the validation data first in order to correctly determine the produced data's accuracy.

Additionally, an extensive validation of GOES-W would be necessary in order to determine how well it performed. This would have been possible in the course of this study, given the data from raw scans and stations that were available, but was not done due to operational

reasons.

As the validation tables show, the satellites with high temporal resolution performed much better than those that only performed three-hourly scans. In a high-quality, global ECV data set, it would be important to maximize the temporal resolution of the data used. One possibility would be to supplement geosynchronous data with AVHRR scans. Another possibility would be to include partial-disc scans next to the full-disc scans. These scans are performed twice hourly and would greatly increase the temporal resolution available for selected areas of the satellites' viewing fields.

Finally, and perhaps most importantly, the issue behind the wash-out effect in twilight scans for GOES imagery would have to be addressed. It is clear that the low quality data produced while the sun is at a low zenith is not a fundamental characteristic of the MAGICSOL algorithm, because it is not visible in the Meteosat imagery. The issue must lie with the software implementation or the different spectral response of the GOES Imager as compared to Meteosat's MVIRI.

It has been demonstrated that GOES imagery can be used successfully to compute CAL, SID and SIS values. If the above issues are addressed, it would be possible to produce data that greatly extends the quality, spatial coverage and temporal depth of our knowledge of the earth's energy budget.

6. Conclusions

This study investigated two main hypotheses:

1. The MAGICSOL method can work effectively with imagery acquired by the GOES satellites
2. The produced data will have a higher quality than other currently available data

Both of these hypotheses could be confirmed within the test month in which the study was conducted.

The data produced using the MAGICSOL method is very promising. Realistic patterns in cloud albedo, direct irradiation and global irradiation could be observed in the results. It was possible to distinguish climate factors and weather patterns across several satellites. Also, the agreement between satellites was very good. The data produced has a higher horizontal resolution than comparable data, and when validated against ground measurements the data produced using MAGICSOL had the highest accuracy scores.

Nonetheless, the quality did not meet the accuracy targets outlined at the beginning of the study. Some improvements still have to be made before high quality, global ECV data sets of CAL, SID and SIS could be produced. The temporal resolution of the input data would have to be increased, perhaps by using partial-disc scans that are conducted during the GOES routine operating schedule or by utilizing AVHRR data, as has been done for the CLARA data set. Also, problems with data produced at low solar zeniths would have to be addressed in order to make data collected during twilight scans useful.

If these issues are addressed, it would be possible to produce long time series of high-quality data of important, yet hitherto lacking or insufficiently measured climate variables.

Acknowledgments

I extend my heartfelt thanks to Prof. Dr. Jörg Bendix, Dr. Richard Müller and Dr. Thomas Huld for their unfailing support in countless technical and theoretical aspects of this study. NOAA, EUMETSAT, CM SAF, ECMWF and LDAS have also earned ample gratitude by gracefully providing large amounts of data, sometimes several times. I also wish to thank the HRZ of the University of Marburg for their understanding and cooperation while my downloads temporarily reduced the speed of the entire university's network. This study was conducted using only open source technologies and would not have been possible without the respective communities, of which a small selection are: R, netCDF, OpenSUSE, LibreOffice, Zotero, GRASS GIS, Python, QGIS and ImageMagick.

Erklärung

Ich erkläre an Eidesstatt, dass ich meine Masterarbeit

**A proof of concept study to use CM SAF's MAGICSOL method to retrieve global and
direct surface radiation from historical geosynchronous observations**

selbstständig ohne unerlaubte Hilfe angefertigt und mich dabei keinerlei anderer als der von mir ausdrücklich bezeichneten Quellen und Hilfen bedient habe.

Die Masterarbeit wurde in der jetzigen oder einer ähnlichen Form noch bei keiner anderen Hochschule eingereicht und hat noch keinen sonstigen Prüfungszwecken gedient.
